Caladium esculentum did finely with a sharp mound of soil over the corms. So also did *Tuberous Begonias*. A sharp well-beaten earth-mound I prefer for these, as preventing too much access of water. *Amaryllis Johnsoni* and its allies all sur-

vived well with the coarse manure cover. Dahlias are commonly left in the ground here, but the losses are heavy from freezing of the buds from which the new growth is made. This could be prevented by the earthen mound, but I can see no advantage in keeping Dahlias over winter outside. I much prefer to lift and divide the roots after sprouting, and this sprouting I defer until as late as possible, so as to delay the flowering to a season more propitious for their flowers than our

Fig. 43.—A Double-flowered Cyclamen, natural size.—See page 234.

hot midsummer. In the warm lands near the coast I have seen Dahlias, that had been left out all winter, in bloom in spring, and the flowers there were fine, but here such tubers will get into bloom in June in our hottest weather, and are poor. By keeping them back as late as possible we can delay the bloom until August, and generally get fine flowers all the fall.

In the matter of trees and shrubbery we have still much to learn about winter protection. Abutilons, with a high mound of soil or sawdust around their base, will usually be killed back only to the top of the mound, and will grow strongly from the base. It is better, however, to cut them down as soon as the frost checks them to within a foot of the ground, and then cover all with earth. Erythrina Crista-galli does finely the same way, but I usually prefer to pot some and start early in the greenhouse for early bloom.

Figs, with large Pine-boughs stuck in the ground around them, hardly lose a bud, while those fully exposed are badly frozen. Tender evergreens, of course, cannot be covered with soil, but I find that Pine-boughs tied closely around Neriums and Gardenias bring them through in fine condition. I have one Gardenia florida on the east front of our college building, in a projection which shelters it from the morning sun, that has been otherwise unprotected, and is all right. The high brick walls around it doubtless absorb much sun-heat during the day and radiate it at night. In the warmer sections of the

Fig. 44.—Proliferous flower of Cyclamen, natural size.

coast country the Gardenia grows almost to a tree-like stature wholly unprotected. Double-flowered Camellias seem more liable to lose their buds in winter than the single-flowered ones. While single-flowered red Camellias are comparatively plenty, it is rare to find a good double variety in the open air. I am sure the trouble mainly arises from planting on the south exposure, as most people are apt to do with half-hardy things. Placed where the morning sun does not strike them, or pro-

tected by evergreen boughs, Camellias would do well in all of southern and eastern North Carolina up to the centre of the state. The perfect hardiness and fine growth of Azalea Indica here makes me wonder that so few are planted. They are largely used in South Carolina, but seldom seen here. The Azaleas which have been blooming this spring in my front yard have attracted much notice, and I have continually to be telling people what they are.

Agave Americana came through the winter without protection in full exposure to sun and north wind, but in a badly battered condition. With a board shelter to keep off sun and rain, it winters finely in dry ground. Musa Sapientum survived with a hogshead inverted over the crown and packed with dry firm straw. We are planting some Richardia Æthiopica in a Lily-pond, with the purpose of letting the roots remain in the mud next winter for summer flowers. In this same pond we had last summer a lot of Pontederia (Eichornia) crassipes. A friend told us they had lived over winter in his pond. We doubted it, and put some of them in a tub in the greenhouse. All that were left in the pond perished, as we expected. Lantanas, cut back and mounded with earth like Abutilons, are all right, and will doubtless prove very efficient with this mode of treatment.

Maltese Oranges of large size, in tubs, wintered perfectly in our cold grapery, and are blooming much better than they ever did in a heated house. Winter-garden possibilities under glass here are immense. There are so many things which the simple glass roof will preserve in beauty that I wonder that so little is attempted in this way. There are, of course, some flowers, such as Violets, Hyacinths and Daffodils, all winter outdoors, but there are times when they are much injured by frost, while the simple glass roof would keep them in constant beauty. Phlox Drummondii blooms all winter in our cold

Fig. 45.—Proliferous flower of Cyclamen, natural size.

Fig. 46.—A small flower from the same plant, twice the natural size.

grapery, as also does Candytuft, Sweet Alyssum and Mignonette. Pansies are gorgeous in the Vine-borders.

It would be easy to make a long list of plants that could be used in an unheated conservatory here, and I have often been surprised that our enterprising proprietors of winter hotels have not struck the idea of a glass-covered garden for invalids as they have the glass-enclosed hotel verandas. I cannot imagine anything more attractive than a large airy conservatory, with everything planted out in a natural way on a lawn of Selaginella. We have a plan on foot to secure such a resort on our beautiful Capitol Square in Raleigh.

Garden Strawberries.

MR. BLACKNAL'S experience with certain varieties of Strawberries, in North Carolina, differs so widely from ours in New Jersey, that I am tempted to offer a few suggestions about the best garden Strawberries. Crystal City has been my favorite kind, notwithstanding it costs twice as much to raise as the average berry, and so long as I could do no better, I was willing to raise it at twenty-five cents a quart for its exquisite flavor for table use. It is a week earlier than any other berry, but if Michel's Early continues to do as well as it did last season, I shall depend upon that for a first early until we get some new variety still better, because, while it lacks a little of the sprightliness of Crystal City, yet it is very sweet and yields largely. I have never found a better second early kind than May King. It is a remarkably healthy and vigorous grower, with berries large, well colored, and as regular as though turned in a lathe. It is fairly productive and very sweet. Bubach No. 5 is a satisfactory mid-season berry, if given high culture, and under such circumstances it makes runners quite freely, but the runners are short-jointed, and where such a variety as Gandy will stretch out its runners two feet between plants, they would be only six or eight inches in Bubach, and this peculiarity causes it to make a handsome, compact bed. For a late fruit Gypsy has more good points

than any other. It is exceptionally healthy and vigorous and extremely productive, and the berries are large, of fine quality, with a glossy surface and rich color. It is, however, a pistillate kind. Cloud has only one recommendation, and that is productiveness. It is small, dull-looking and very poor in quality, and makes an immense number of small plants.

Pistillate varieties sometimes produce good crops when planted alone, and they are probably more likely to do so on rich land; but when such a result happens, it must, of course, depend on one of two things—either there must be some perfect flowering variety sufficiently near for insects to carry the pollen, or there must be enough development of stamens to effect fertilization. The last tendency varies considerably with different pistillates, and neither is fully safe to rely upon. It is much better not to allow the runners to grow than to thin out the plants, because it exhausts the plants largely to produce them. With such free-running plants as Crescent, I have found it a good plan to plant three feet apart each way, and then allow the first runners to grow, placing the young plants, as they form, in the row, in such manner as to have them about six inches apart, leaving a space of fully three feet between rows for cultivation, and, after this, remove all runners as fast as they show themselves. If the land is thoroughly enriched, they will produce big berries, and plenty of them. Of course, to secure the finest fruit, some clean mulch must be applied between the rows. The ideal mulch would be something, which, while it shaded and kept the soil cool and also protected the berries from the scorching sun, would still allow the rains to soak down freely and also a free aeration of the ground. Growing grass, not too thick, accomplishes this, but it draws both fertility and moisture, which makes it objectionable. Perhaps, where obtainable, Pine-needles, with a rank growth of foliage to shade the berries, come as near to meeting all these demands as anything we can use.

Hamonton, N. J.

Wm. F. Bassett.

Notes from the Harvard Botanic Garden.

FEW plants which flower in early spring are so much admired as *Adonis vernalis*. It belongs to the *Ranunculus* family, a native of southern Europe, and was introduced into English gardens 250 years ago. It grows from ten to twelve inches high, and the finely cut leaves are produced in whorls on the stem. The large yellow Anemone-like flowers, which are from two to three inches across, are produced one on each stem. It will grow in almost any soil, but to have this beautiful plant in perfection it ought to be grown where it can get plenty of sun, in good, rich, moist, sandy soil, and not often disturbed. It is propagated by careful division in the fall or by seeds.

The beautiful alpine Primrose (*Primula rosea*) has proved hardy here with a slight covering of leaves. It was sent to England in 1879 from the Himalaya mountains, where it was found growing from 10,000 to 12,000 feet above the sea, and also from Afghanistan, where it was collected on snowy ravines at 11,000 feet above the sea. It has a very neat habit, the leaves, which are pale green, being about four inches long, and forming compact tufts. The flowers are produced in heads like the *Polyanthus*, and when first expanded are carmine-pink, but gradually grow pale with a shade of purple. The flower-stem is from four to six inches high, and the single flower is nearly one inch across. In its native country it flowers from June to August, but here it flowers during April and May. It is planted here in a rather shady position in good rich loam. This beautiful little gem should be in every collection, and can be easily raised from seed.

The pretty little *Anemone ranunculoides* is growing in a rather sheltered spot here, where it has a covering of leaves thrown over it every winter. This is taken off in the middle of March if the weather is favorable, and in a few days after the plant is covered with its beautiful yellow flowers. It is a tuberous-rooted European species, very like our common Wood Anemone, but has rather coarser foliage, and the flowers are bright yellow instead of white or rose-colored. It grows from four to six inches high, and the flowers are produced either singly or in pairs. It is frequently cultivated in English gardens, and is also naturalized in some English woods, but is seldom seen in cultivation here. It grows well in a shady position with a well-drained sandy soil, and is propagated by division.

Alyssum saxatile has been in cultivation for over one hundred and fifty years, and it remains one of our most valuable early spring-flowering plants. It is somewhat shrubby at the base, and grows about one foot high. The golden yellow

flowers are freely produced in loose panicles, and if the weather is good they last in perfection for two or three weeks. It will grow in any sunny position with light sandy soil, yet it is seen to best advantage when it is planted in a sunny situation on the rock-work, where its prostrate stems can hang over the stones. It is easily and readily propagated from cuttings or seed.

The Spring Garden.

THE Irises are now represented in the garden by the dwarf forms of the rhizomatous kinds. The first of these to flower is *I. Chamæiris*, a dwarf plant six to nine inches high, leaves broad, flowers a primrose-yellow, with light brown linings, orange beard, standards broad and well incurved. This is followed by *I. lutescens*, a slightly lighter yellow-veined brown, with yellow beard, standards not so broad as those of *I. Chamæiris*, and leaves narrower. *I. Olbiensis* is also dwarf, six to nine inches high, with broad short leaves; flowers purple, with a metallic lustre, and falls a very deep rich purple; a very attractive variety, and much like *I. nudicaulis*, of a similar, though not so rich a color, but with a more graceful habit of flowering and a trifle taller. *I. pumila* is one of the first of the group to flower. This well-known kind may be had in various colors, the type being a rather dull purple. The variety *Alba* is far from being a satisfactory white, the color being a dirty cream, dull and indistinct. *I. Sibirica* is one of the most attractive of those now flowering. It has narrow, erect standards, oblong falls veined with violet on a light ground. The leaves are narrow and rush-like, and in the variety, *Hæmatophylla*, they are stained a deep blood-like tint. The plant is from twelve to eighteen inches or more high, and very ornamental.

Rather handsome flowers are those of *I. oxypetala*, a beardless Iris with erect standards and narrow falls, of a beautiful soft light, violet or lilac shade, centres of which have a yellow ground reticulated with brown. The leaves are narrow and rush-like, and 1½ feet long. *I. Missouriensis* is of similar color and form, but without yellow, and rather more distinctly reticulated. Both of these are very desirable Irises, as is the lovely little Crested Iris of North Carolina, which is just opening. Nothing could be prettier in the season than a very dwarf border of this gem, with its bright flowers.

The first of the Germanica section are now showing color, and very soon the garden will be gay with a wealth of their showy flowers. Tulips are still in force, and whether they are interesting or not will depend very much on the varieties grown. A bed of Van Thol Tulips, such as ornament our parks in the spring, seems to me neither a work of nature or art. It certainly is not for lack of material that we are favored with plantings of yellow, red and white dwarf Tulips in hideous regularity. Nothing is more formal than a bed of the same class of Tulips, but this is formality and crude color combined. When we can arrange our own plantings we can arrange them with more unstudied art and use the various sections and species to give a less drastic effect, and by the successive flowering enjoy their brilliant colors for a long season. Why plant a Tulip-bed which shall be at the mercy of one shower? Among the kinds of Tulips which should always be planted are the Byblooms, Bizarres and Roses, the flowers of which are richly colored and late. Breeders, too, should be in all gardens. Good forms of breeders are not only beautiful, but interesting. These, of course, are richly colored selfs which have not yet rectified or taken on their true coloring. Seedlings I do not fancy so much, the "dropper" habit being more curious than satisfactory. Some seedlings of T. Gregg, which have been in my border four or five years, still keep up this habit, and so far do no more than show their prettily spotted leaves. Of other species, T. Gesneriana is one of the handsomest common kinds, but there are numerous smaller species which are full of interest. The florists' Tulips seem far enough away from some undetermined ones from Asia Minor, which form a very pleasing, graceful group in the border. These have narrow, very slightly glaucous leaves, and the small flowers are borne on flexible scapes. The colors are very peculiar shades of reds and yellows quite beyond me to describe. Other forms from the same section are dwarf, with rigid scapes, glaucous foliage and vivid crimson flowers. All have the sharp-pointed petals abhorred of the florist. In another respect this red variety differs widely from the hybrid Tulip in having a very thick felt-like tunic instead of the thin skin of the latter—from which I am inclined to think they will do better in a somewhat drier place than the full exposure of the garden, though they seem hardy enough.

Elizabeth, N. J.

J. N. Gerard.

The Wild Garden.

CLUMPS of Daffodil are found growing in moist meadows in the south of England and in many parts of Europe, and they can be very appropriately used in harmony with similar natural features here. On lawns they seem quite out of place, and it is in the wilder parts of the garden where they can be used most effectively. The best opportunities for developing a wild garden, by the natural disposition of suitable plants, are found outside of the limits of the kept grounds, and, where woodland abounds in the immediate vicinity, great care is required in the changing of the natural features not to draw the line too sharply. Many years ago the owner of this estate planted a space in the wilder part of the garden with a few native plants. The group includes the American Cowslip (*Dodecatheon Meadia*), the Closed Gentian, *Cypripedium pubescens*, *Aquilegia Canadensis*, *Adiantum pedatum*, and *Smilacina racemosa*. They are all thriving to-day without any special care.

It is a fact that many of the most beautiful and tender dwarf herbaceous and alpine plants do better when planted in grass, and disturbed only to free them from weeds. Such a lovely, yet fragile, plant as *Anemone deltoidea* can never be satisfactorily cultivated in an ordinary rock-garden, but if planted in a rather moist grassy spot it will thrive nicely. The same may be said of the pretty yellow *Anemone ranunculoides*, and, for that matter, all the *Anemones* belonging to the *nemerosa* type. *A. Pennsylvanica* is perfectly at home in the wild garden, and, in fact, it ought never to be cultivated, in the strict sense of the term. It is a species well worth growing, too, and gives a multitude of pretty cup-shaped white flowers, which are excellent for bouquet-work. It is liable in time, however, to become a nuisance, by monopolizing the territory allotted to other plants. *Viola pedata*, and especially the varieties *alba* and *bicolor*, and *V. lanceolata* are bright and unobtrusive little plants, as also are the Bluets (*Houstonia cœrulea*), although there may be some objection to the use of these where they are common in the vicinity. The star-shaped flowers of *Sanguinaria Canadensis* are strikingly bright. They come year after year and interfere in no way with the verdant aspect of the place they occupy. *Arenaria grammifolia*, *A. montana*, *A. verna* and *Stellaria Holostea* form neat white patches when in bloom, and afterward assimilate with their surroundings so well that their presence is not noticeable. So also do the common Moss Pinks, which just now are a blaze of color. The common *Silene Pennsylvanica* and the rarer Fire Pink (*S. Virginica*) are more at home in such a place than under cultivation. The double-flowered *Genista tinctoria* will be a perfect sheet of yellow while it lasts, and as it is a neat prostrate shrub looks quite natural when out of bloom. There are, also, in addition to several kinds of *Narcissus*, many other bulbous and tuberous-rooted plants which can be effectively used. These include the American Dog's-tooth Violet (*Erythronium Americanum*), Spring Beauty, *Claytonia Virginica*, *Dicentra Canadensis*, *Rhoxia Virginica*, *Calopogon pulchellus*, *Tulipa cornuta* and *T. suaveolens*. Plants used in this way want intelligent care, attention enough to protect them from crowding, or any such change in the natural features of the place as will make the wild garden look in any way artificial.

Where practicable, with sufficient shade, *Kalmia latifolia*, *Andromeda floribunda*, *A. Catesbæi*, *Rhododendron villosum*, *R. Wilsoni* and *R. ferrugineum* and choice broad-leaved evergreen shrubs may have a place, and where there is more sunlight flowering shrubs can be used.

Wellesley, Mass.

The Forest.

The Forests of California.—II.

OUR issue for May 4th contained portions of a paper on this subject, read before the American Forestry Association at Washington by Hon. William Alvord, and the following are additional extracts from the same paper:

The Big Trees (*Sequoia gigantea*) have been discussed so thoroughly, especially by Dr. Gray in his essay on "The Sequoia and Its History" and by Mr. F. J. Walker in his admirable paper on "The Sequoia Forests" that little needs to be added here.

They are not found in any other part of the world, and in California only on the westerly slope of the Sierra Nevada, where they occur in groups, standing at intervals along a zone varying from 5,000 to 7,000 and 8,000 feet in height and extending for a distance of 200 miles.

In the Calaveras Grove, the farthest north and the first dis-

covered, there are standing 103 trees, twenty of which are about twenty-seven feet in diameter and 250 feet in height, and a number of prostrate trunks, which appear to have been much larger when in their prime.

One of the fallen trees in this grove is estimated to have been about 400 feet in height and thirty feet in diameter; the tallest in this grove is 260 feet, and in the Mariposa Grove 272 feet, and in the King's River Grove 300 feet. The thickness of the bark is sometimes two feet. In estimating California's lumber resources these trees have been left out, because the wood was not considered worth much for that purpose. Up to the present time some lumber, but not much, has been cut from the Big Trees in the counties of Fresno and Tulare, in amounts not to exceed, in all, 30,000,000 feet, some of which, on account of its finer grain, is now preferred to the Coast Redwood for interior finish, and has been sold for \$40.00 a 1,000 feet in San Francisco. The largest body of *Sequoia gigantea*, and of the densest growth, and perhaps containing more trees than all the other Big Tree groves in the Sierras combined, is on the seven-thousand-acre tract in Converse Basin, on King's River.

That these trees are very old is evident, but the annual rings are not clearly discernible throughout an entire section, therefore there are variations in the opinion of investigators; some hold that they are 4,000 years old, while others think that an overestimate, but it seems as if sufficient was known for us to fairly consider them as old as the Christian era. Dr. Gray beautifully says: "It is probable that close to the heart of some of these living trees may be found the circle that records the year of our Saviour's nativity." The Redwood grows from shoots and seeds and bears egg-shaped solitary cones about one inch long, but *Sequoia gigantea* grows from seeds only, and its cones are remarkable for their small size, being only one to one and a half inches in length. You may get an idea of their size by the average English walnut of commerce, which they resemble, although more oval.

The Redwood (*S. sempervirens*) is another noble tree, and its habitat is restricted to California and not broadly disseminated there; on the contrary, it is confined to a narrow belt of country lying along the sea-coast, its reach inland being nowhere more than forty miles, and generally not half so far. It may be said to reach from the ocean on the west to the summit of the Coast-range on the east. Beginning in Del Norte County, occupying the north-western angle of the state, the Redwood belt extends, with some gaps, down the coast four hundred miles, to Santa Cruz, where, it has been said, is the southerly limit of its growth; but I have recently seen some trees in San Jose Cañon, several miles south of Carmel Bay, and there is a grove of Redwoods about thirty-five miles still farther south, on the South Fork of Sur Chiquito, a good-sized trout-stream running through narrow cañons from its source to the ocean, the North and South Fork coming together about three miles from the ocean. The trees average smaller than those growing north of the Golden Gate, but Mr. F. S. Douty measured one that was thirty-eight feet in circumference five and a half feet from the ground.

Along the central portion of its range the Redwood occupies the ground to the almost entire exclusion of all other trees. Its distinguishing features are the great size of the trees, their amazing vitality and the thickness with which they stand together. Search the world over, and nowhere else will you find such an amount of timber to the acre. The trees vary in height from 180 to 250 feet, and in diameter from nine to twelve feet. They stand so thickly along the central portion of their range that there is hardly space for a team to pass between them. Twelve miles from Boulder Creek, Santa Cruz County, and less than one hundred miles from San Francisco, there is a Redwood-tree, called the "Father of the Forest," which is said to measure forty-two feet in diameter at its base, and twenty-eight feet five feet from the ground, and is nearly three hundred feet in height; the "Mother of the Forest" measures twenty-four feet in diameter.

In an acre of woodland near Highland, in Santa Cruz County, Mr. W. E. Emery and a friend counted two hundred and thirty-six trees from one and one-half to eight feet in diameter, and they estimated that a single tree of the latter size would produce from 15,000 to 20,000 feet of lumber, and from such an acre might be taken a quarter of a million feet, but the average yield per acre in lumber is 25,000 feet in Mendocino, Sonoma and Santa Cruz Counties. In Humboldt County some acres in flats along streams will yield as much as 500,000 feet, but careful conservative owners of Redwood-lands in that county estimate 60,000 feet as a fair average of lumber per acre. There are of these Redwood-forests more than two million acres, two-thirds of which are densely timbered.

The Redwood, as its scientific name imports, is exceedingly tenacious of life. Cut it down and numerous sprouts shoot up from its roots, and in a short time grow so thick as to hide the monster stump, and only repeated cuttings of these young shoots suffice to repress the tendency of the tree to reproduce itself. The wood is durable, light, splits freely, but is not very strong; nearly all the lumber used before the days of saw-mills was riven from this tree. A dealer in lumber in San Francisco recently filled an order from London for 100,000 feet of Redwood-lumber, cut from the bole, the stump and gnarl chunks, for use in houses, as inside finish in natural wood, and for furniture and cabinet-work. It is so good and handsome for such purposes there is no doubt that the export demand for it will increase.

T. H. Hittell, the historian, says: "In the eyes of many persons the Redwood is the most beautiful tree that grows, and the Redwood forest is the most beautiful forest in the world." Nearly all the land upon which the Redwood grows having passed into private hands, these forests are doomed to early extinction unless state or national pride and the good sense of those in authority authorize the purchase of a portion of them for public reservations.

The Port Orford Cedar (*Chamæcyparis Lawsoniana*), though really belonging to the forestry of Oregon, is mentioned here because there are a few groves in California about Mount Shasta. It is a large tree and very valuable, makes white lumber, hard but easily worked, takes a very fine polish, excellent for interior finish, also for flooring, ship-building, does not decay rapidly in the ground, and so is used largely for fence-posts. It grows from 130 to 180 feet in height, and is from five to ten feet in diameter. When young, like the specimens in the Golden Gate Park, about twenty-five feet in height, the trees are very handsome, the foliage drooping, and so thick as to hide trunk and limbs and touching the grass, make a graceful addition to the beautiful lawn.

The Madroña (*Arbutus Menziesii*) is a handsome evergreen tree, reminding one of a Magnolia, about fifty feet in height, with hard and strong wood and smooth brownish red bark. There is one of extraordinary size near the reservoir on Mount Tamalpais, Marin County, which is seven feet in diameter in the small part of the bole, and several branches measure from one and one-half to three feet in diameter. The bark is in demand by tanners, and the charcoal is sold to manufacturers of powder.

The California Laurel or Bay-tree (*Umbellularia Californica*) is a Coast-range evergreen tree, two to four feet in diameter (sometimes larger), fifty to eighty feet in height; leaves plentiful and strongly aromatic; wood light-colored, close-grained, takes a very high polish, and is valuable for wainscoting and cabinet work, and is quite as handsome as Satin-wood.

One is attracted to the lumber-forests of California by their agreeable shade, cool clean grounds, resinous odors, and the knowledge that one will not find annoying insects or reptiles to trouble, nor will timid tourists find wild animals to frighten them. Much has been said about the wasteful methods of our people in dealing with their forests and forestal products; while these methods cannot be altogether justified, something may be said in their extenuation. Judged by ordinary criterions, it would be an easy matter to convict our people of other excesses than these. We were at first just as prodigal in disposing of our gold-bearing deposits as to the casual observer we may seem to have been in disposing of our forest-resources. The pioneer miner worked only the richest portions of the gold-bearing gravel, leaving the poorer untouched, nor did he work the richer ground with much closeness, simply because it would not pay to do so, food was so high.

When it came to settling upon and cultivating the land a like policy was pursued—the more fertile and accessible being chosen, and the poorer neglected. So with the pioneer woodman, needing lumber, he picked out and felled the best trees, and from these selected the parts that suited him the best; this culling and rejecting was but a rude sort of thrift; why should he accept the poorer when there was enough, and, to his mind, an inexhaustible supply of the best?

But, however it may have been in the past, there is but little of this timber-devastation now going on in California on account of the more accessible lumber-forests having become private property, and the owners are careful to guard against any undue waste. Then, much of the tree that was formerly rejected as valueless is now utilized by the millmen, the creation of new uses for the inferior lumber and the employment of improved machinery having made this possible. Into our larger mills improved mechanisms are constantly being introduced, so that even the smaller economies are not neglected. In this manner the percentage of material in the standing tree

has been increased twenty to thirty per cent. As in the mills, so in the logging-camps, the tendency is toward economy, both in saving the raw material and in the cost of handling it.

The continued prosperity of California depends upon its mountain-forests. They should be well protected, and extended where possible, and this truth should be constantly reiterated and amplified.

Correspondence.

A Greenhouse for Amateurs.

To the Editor of GARDEN AND FOREST:

Sir,—I have long desired a small greenhouse for propagating and cultivating a few plants, but have been deterred by the probable trouble and expense until last autumn, when I began to study the matter. Among other authorities consulted, I found in GARDEN AND FOREST, vol. iv., pages 55 and 67, an article entitled "Plant-houses for Amateurs," in which Mr. Gerard gave much of the information I wished. This was deficient, however, in its instructions on several points where novices need information, and I have therefore thought that my experience during the past winter might have some value.

In the first place, as to location, the greenhouse should be as near the dwelling as possible. This will be found essential to the comfort of those who intend to do their own work. The exposure to the tempestuous nights of winter for the necessary attention to the fire will be lessened by this propinquity. Of course, the structure should face north and south, and if possible should be protected by some shelter from the north and north-west winds. My own greenhouse is placed on the eastern end of a children's play-house, with which it is connected, while a belt of evergreens sheltered it on the north. The advice of Mr. Gerard was followed as regards size, and this resulted in a span-roof house with seven-foot ridge, eighteen feet in length by ten feet in width. The sash extends fifteen feet, and it is boarded for three feet at the western end. The side walls are of hemlock-boards covered with building-paper and clapboarded with the best material. Upon the inner side the walls are sheathed with matched pine-boards. In addition to the five three-foot sashes on east side, which are hinged at the top, so that they can be lifted, the eastern gable end is of glass, for which the sash was necessarily made expressly. In this one or two panes were made to slide for ventilation. For the foundation, timbers were laid upon cedar-posts, set deep enough to be secure from frost. Of these there were three on each side. As the surface of the ground fell off to the east and north, and in order to bring the building on a level with the play-house, a stone wall was needed. For this purpose a ditch was dug under the outer walls of sufficient depth and filled with small stones, which serve also as a drain for surface water. Upon this were built the walls of common field stone, laid in mortar, and pointed inside and out. The enclosed area was then filled with good garden-loam, thrown in before the sashes were put on, to a level with the base of the wood-work. This was an expense which would not have been required on level ground. The building is all the better as to durability, but the cedar-posts under ordinary circumstances would answer every purpose. The foundation-walls upon the outside were banked and sodded for increased warmth and for appearance.

The greenhouse proper was securely fastened to the play-house by continuing the timbers and shingled roof, thereby affording an additional length of about eight feet in front for a potting-bench, with ample room beneath for potting material, pots and a box for coal. Entrance from the outside was obtained by a common battened door, and this cosy little space was well lighted by a four-foot sash placed lengthwise. At the back of this room, separated by a partition from the plant-house, was placed the stove. One coat of white-lead paint was given to all the wood-work outside and inside.

As to heating, since the hot-water apparatus, with its stove or furnace and expansion-pipe, is thought the best by florists, I assumed that it was best for my purpose. Fortunately, I heard, by chance, that several Baker heaters, formerly used by a railroad company for warming passenger-cars, were for sale at a low price. One of these, in excellent condition, with the expansion-pipe, was accordingly selected, and, being already jacketed, was exactly the article for my house. A simple stove-pipe was passed out through the roof and carried up sufficiently high above the adjacent play-house to secure draft. The heating-pipes consist of a single two-inch flow and return, connecting with a series of five pipes, which completely encircle the house.

The whole apparatus has been most successful, giving, with a moderate fire of anthracite, a night temperature of fifty degrees during the coldest weather. The amount of fuel consumed has not exceeded on the average more than two common hodfuls in the twenty-four hours. The supply of water for the plants was afforded by sinking a common whisky-barrel in the ground beneath the benches, and filling this by means of a portable hose, connected when needed with the faucet in a neighboring stable.

In the arrangement of the interior of the greenhouse a bench was constructed on each side, three feet high, with a depth of four feet, the hemlock-boards being cut off this length and placed within a half-inch space and left movable. The supports are of galvanized iron half-inch pipe, which are neater, stronger and more durable than wood. At the extremity of the northern bench nearest the stove a space of about four feet in length was reserved for a propagating-bed, the bottom being of common roofing-slate, and the area beneath boarded in to confine the heat.

The central walk of two feet in width between the benches has a flooring of North River flagging-stone, laid down without cement. The greenhouse cost slightly more than two hundred dollars. It might have cost less, especially in the arrangement of the heating-pipes, in which experience on my part was wanting, but I am satisfied. The house has been an unending source of pleasure to us all. An abundant supply of common window-plants has been propagated by cuttings, various kinds of seeds have been raised, and the area below the benches devoted to various Ferns, running plants and shade-loving vegetation, while *Tropæolums* and other vines have been trailed along the centre overhead—all, too, under the sole supervision of a daughter, whose tastes have thus been gratified, as may those of many other of our female readers.

No Flowers Sold in the Streets of Boston.

To the Editor of GARDEN AND FOREST:

Sir,—All those who love the spring and its flowers must feel like remonstrating against the exclusion of the flower-venders from the public streets in Boston. A week ago they were like a garden. There were May-flowers and Daffodils everywhere inviting every passer-by to take them, or at least to take a look, and carry away a memory of spring. Here was a boy with great bunches of Roses, Carnations, Sweet Peas and Ferns, and purple Pansies "for thoughts"; and there were more boys with Marsh Marigolds to remind each man who passed of the brooks and meadows as he knew them in his boyhood. Everywhere there were women with a handful of flowers to offer, flowers of the field and garden and wildwood—all with suggestions of the country and the spring. But these are all gone—boys, flowers, and smiling, interested women and the pleasant thoughts suggested. There are some florists' windows left to look into, and these are beautiful, but the plate-glass window will not allow us a touch or smell, and the sight alone brings no thrill of remembrance and delight. Nowadays, when it is held that beauty is a great educating force, should we not protest when so much of it is swept away from the streets where every one can enjoy it?

Recent Publications.

The Genus Masdevallia. Issued by the Marquess of Lothian, K.T., chiefly from plants in his collection of Orchids at Newbattle Abbey. The plates and descriptions by Miss Florence Woolward, with vignette engravings from photographs, and additional notes by Consul F. C. Lehmann, German Consul in the Republic of Colombia. Dedicated by permission to Her Majesty the Queen.

The first two parts of this remarkable book have just been sent out to subscribers, and may be procured from Mr. R. H. Porter, 18 Princes Street, Cavendish Square, London, at the price of £1 10s. each. It is intended to be published in about twelve parts, each containing ten folio plates, and from what we know of its authors we may fairly believe that it will be completed in a reasonable space of time. The genus *Masdevallia* is one which, on account of the extreme delicacy, beauty and curiosity of its numerous species, and of the difficulty of introducing and cultivating many of them, is of great interest both to botanists and Orchid-growers, and well deserves the pains and skill which have been lavished upon it by the authors, both of whom have done their parts remarkably well. For, though neither of them lays claim to the title of botanist, yet the book is one which will be indispensable both to bota-

nists and horticulturists and to those who love illustrations of beautiful plants. The drawings, lithographs and descriptions are the work of a lady and an amateur, but the book will take high rank among the most beautiful scientific works of the century. Miss Woolward's drawings are not of the style which is affected by some artists of her sex, who sacrifice exactitude of structural detail to artistic effect; they are, on the contrary, of a more botanical character, and though in some cases there is a certain stiffness about them which the artist pure and simple might criticise, yet they are most faithfully drawn and colored from the living examples, and show the curious and minute details of structure in these wonderful plants in a way that no ordinary artist, however skillful, could have done. The Marquess of Lothian, whose love for these delicate plants has led him to devote to their cultivation the leisure snatched from the numerous and pressing engagements of a minister of state, is fortunate in having found an artist of such ability and industry to draw and describe them. We have recently lost Miss North, who was distinguished above all her sex as a traveler and painter of floral beauty, but we may say that in Miss Woolward a most worthy successor has appeared, though her drawings are of a totally different character. It is unusual to find a lady who can look at plants in the truly scientific spirit which Miss Woolward shows, and so far as we know she is the first who has combined with this spirit the power and will to carry out such a work as this in a thorough manner. Laboring under many difficulties which only those who have had experience in similar work can realize, and deprived by the extraordinary will of the late Professor Reichenbach of access to the collection which was almost indispensable to a complete knowledge of this genus of Orchids, it was not possible that this monograph should be absolutely complete; but it is a work which will astonish many who only know the few species of *Masdevallia* which are found even in large collections of Orchids.

The co-operation of Consul Lehmann, who perhaps of all men knows most of the plants in their native country, and his notes on the climate of the localities where *Masdevallias* grow, will be of great use to cultivators. The bibliography, synonymy and descriptions appear to be most careful, concise and systematic, the history of the plants is given as far as known at present, and we are sure that any collectors or growers of these plants who possess rare species will do well to communicate with Miss Woolward, and, if possible, send her flowers of unknown or doubtful species.

Such a work as this, together with the excellent manual of Orchidaceous plants which is being published by Messrs. Veitch & Sons, of London, aided by the activity and enterprise of Orchid collectors in South America, will, no doubt, increase the number of amateurs who devote themselves to the study and cultivation of these plants.

The twelfth bulletin of the *Salem Public Library* is devoted to botany, and contains, first, an introduction in which some sound advice on reading in botany is given; second, a special reading-list of botanical works, and third, a special reading-list of works on agriculture and gardening. "Botanical reading," the introduction tells us, "may be of two sorts. We may read to obtain a knowledge of the structure, physiology and uses of plants, or to become acquainted with the plants of certain regions. In either case some general knowledge of the natural divisions of plants is essential, but even before this knowledge can be obtained there must be a thorough understanding of the simple elements of botany, so that the terminology of certain advanced books may be readily comprehended, for in every branch of science there are terms which must be continually used, and the author must take for granted a certain amount of elementary knowledge on the part of the reader of the methods of treating the subject. Botanical reading—in fact, all reading on subjects of natural history—should be accompanied by continual examinations of specimens, living specimens wherever possible, in the case of plants and animals, with the aid of a magnifying-glass when required." And the bulletin goes on, sensibly, to insist "that the gardener, florist, woodsman and carpenter will work more intelligently with the aid of a course of botanical reading. Our walks to and from business in our city streets can be made more interesting, and the study of their daily changes and growth will awaken a desire to know more of plant-life generally—at least, to cultivate a quality of observation." The special reading-lists seem to us to be admirably selected and to cover the entire field, embracing not only physiological and structural botany, but such special subjects as the Evolution of Plants, Descriptive Botany, Trees (American and Foreign), Grasses, Cryptogams, Ferns, Mosses,

Lichens, Fungi, Algæ, Geographical Distribution of Plants, Local Floras of Essex County, and the Floras of the principal geographico-botanical regions of the earth, Fossil Botany, Economic Botany, Folk-lore, a list of serials, works on Floriculture, Landscape-gardening, Forestry and Fruit-raising. Altogether, this is one of the most intelligently prepared and helpful aids to a study of botany which have yet come to our notice.

Notes.

Owing to the appearance of the *Phylloxera* in California, Grapevines from North America are now rigidly excluded from the territory of the French Republic.

Mr. H. E. Van Deman, Pomologist of the Department of Agriculture, writes to the *Florida Agriculturist* to protest against the use of the name Grape-fruit and to insist upon the name Pomelo, which is appropriate, distinctive and the one commonly used in the East Indies for the delicious fruit which is found in increasing quantity every year in our northern markets.

We have seen no more beautiful Pansies this year than some which were sent to this office by Mr. D. K. Herr, of Lancaster, Pennsylvania, and which were grown out-of-doors in ordinary garden-soil. The delicate markings in some of the newer strains of Pansies, like Bugnot's and the improved Trimardeau, are among the most interesting products of carefulness and skill in selecting and cultivating garden-flowers.

The correspondent of the London *Garden* writes of the Waban Rose, which was exhibited at Drill Hall not long since, that it fully justifies the praise it has received in this country, retaining as it does the matchless form of Catharine Mermet, of which it is a sport, and a color some shades deeper. It is predicted that, like The Bride, another sport from the same variety, it will be esteemed among the choicest of the tea-scented Roses.

A great many of the ordinary bedding-plants, like Zonal Pelargoniums, Heliotropes, Verbenas, etc., receive a severe check or die outright if they are suddenly exposed to the outdoor weather, especially when cold rains or high winds follow. All plants of this sort should be gradually hardened off until they are inured to outdoor conditions. When tender plants are taken out of the house or pit and placed in the open ground the common mistake of watering them too freely should not be made.

The editors of the *Revue Horticole*, in speaking of the different varieties of the Althea (*Hibiscus Syriacus*), remark that the single flowers are generally the brightest in color. The pure white variety, known as Totus albus, is considered the best, and the following double and single varieties are recommended: Albus plenus, Pompon pourpre, Purpureus plenus foliis variegatis, Cèleste, Lady Stanley, Duc de Brabant, Charles Breton, Pæoniciflora, Leopoldi, Comte de Hainaut, Ranunculiflorus albus, Violet simple, Cœlestis simple, Speciosa rubra, Violacea variegata, Carneæ plena.

Commenting editorially upon the proposition that a special exhibit of roadways, pavements and road-making processes and materials shall be made a prominent feature of the World's Fair at Chicago, the *American Architect* says that such a display would come under the eyes of myriads of our fellow-countrymen "who have never seen a decent road and have no conception of the method of making one. If the exhibition should contain nothing but this, it would be worth holding, for it is no exaggeration to say that the question of roads is the most important one to be solved in this country."

In the *Transactions of the Indiana Horticultural Society* for last year, which has just been received, there is a list of the trees of that state prepared by Professor Coulter, of Purdue University. One hundred and eight species belonging to fifty-two genera are mentioned, so that Indiana is behind several of the other states in the variety of its arboreous flora, and notably of Arkansas, which has one hundred and twenty-seven species on the list made by Professor Harvey. There are few states, however, where so many of the trees attain so large a size. Forty-two species are named which attain a height of a hundred feet or more in the Lower Wabash Valley, and thirteen are mentioned as growing more than one hundred and fifty feet high. The figures are taken from actual measurement, but since few trees were measured, compared with the vast number of matured trees which are cut down in a single

year, Professor Coulter thinks that it is quite improbable that the largest individual of any species which has stood in the Wabash Valley within the last twenty-five years has been measured. The tallest tree mentioned is a Tulip Poplar, which was one hundred and ninety feet high. This tree was twenty-five feet in circumference above the swell of the roots, and the height of the trunk to the first branch was ninety-one feet. The next tallest tree measured was a Scarlet Oak, the third a Pecan, and the fourth a Cottonwood.

At a recent meeting of the Nantucket Improvement Association a vote was passed urging upon the members of the Congressional delegation of Massachusetts to resist all attempts to encroach on the public lands of the Yellowstone Park reservation, and quoting from the article which appeared in these columns on the 20th of April last, the resolution goes on to declare that, "This reservation is important as a means of protecting the head-waters of one of the largest and most useful rivers of the country; as a region where some of the grandest scenery of the world is located; as an extensive tract of forest, mountain and valley in which may be preserved, for all time, fine and numerous specimens of the flora and fauna of the Rocky Mountain regions." The Nantucket Improvement Association, which last year was active in creating public interest in national forest-preservation, is now urging all organizations similar to its own to appeal to members of Congress "in order to secure the general and widespread expression of a desire for the protection of the public interests against personal encroachments upon the same."

We have heard it suggested several times recently that the spring coloring of the foliage of the trees is more beautiful than it was in former years, and inquiry has been made whether there is not some climatic change either in the character of the winters or perhaps in the autumn, when the wood ripens, to produce this effect. It is very difficult to remember one year just how the trees looked a year ago, and it is probably the truth that the leaves are no more beautiful this spring than they were last. Perhaps it is true that there is a growing admiration and affection for natural beauty, and it certainly is true that there is a growing taste for more delicate tints and textures. The autumn woods have a glory of their own which compels the admiration of every one, but the soft spring colors make an equally impressive appeal to the eye and to the imagination. Of course, the tender greens predominate, but yet they appear in a variety which is almost infinite, while the bronze of the White Maples, especially when the sun is shining through the leaves, has a marvelous depth and richness. No words will avail to describe the tender pink on the border of the young leaves of the White Oaks, which is subdued as if it had a veil thrown over it so as to make it blend more perfectly with the soft silvery gray of the body of the leaves. This delicacy of coloring is matched by the exquisite and downy fineness of the surface texture of the foliage, and the almost fragile beauty of the tint and tissue of the leaves is heightened by its contrast with the gnarled and sturdy strength of the tree which bears them.

English lovers of the Daffodil have begun to inquire whether the newer varieties which are put on the market every year are really improvements on the old sorts. Some of these novelties are said to have feeble flowers of little substance and a delicate appearance, quite inferior to the rich yellow color and noble bearing of the older kinds. Again, in the rage for something new, the trumpets of some of the recent kinds have been developed into shapes that are almost monstrous. As developed by nature the flower in color and shape has acquired a perfect balance and complete adaptation to its conditions, and although in many instances human selection may transform wild flowers into something more beautiful than the original, yet there is a point beyond which change does not seem to be improvement. Certainly the wild English Daffodil or the Poet's Narcissus, which are both natural forms, are lovely enough, so that it is hardly worth while to pay enormous sums for bulbs that bear less beautiful than these simply because they are new. Buyers are now confused by hundreds of different sorts which are sold under fancy names, when perhaps a dozen, or at most twenty, distinct types for varied and successive planting will answer most purposes for ordinary gardens. While all this is true, there is another view of the case. It is this care for nice distinctions which stimulates observation and study among those who become authorities in judging and cultivating any class of flowers. They not only take pleasure in noting all the varietal peculiarities of their chosen flowers, but others learn from them, and it is to specialists, after all, to whom we look for the advancement of horticulture in all its branches.

The Boundaries of Yellowstone Park.

IT is hardly safe to prophesy what this Congress will do in regard to the boundaries of Yellowstone Park, but the situation just now is this: In the House of Representatives Mr. Stockdale's bill, which is in the interest of the so-called Montana Mineral Railway Company, and gives them the exclusive privilege of using the park as a railroad thoroughfare, has been favorably reported, and is now on the calendar. The Senate has passed the bill presented by Mr. Warren. This cuts off a small portion of the park north of the Yellowstone River in order to give facilities for building railroads to Cook City without invading the park territory, and it adds to the park some 1,200 square miles, although the addition does not include more than one-half of the forest-reservation which was set apart by the President, while the portion of the reservation not included in the park is restored to the public domain. We should prefer very much the original bill of Senator Vest, which included within the boundaries of the park the entire reservation made by the President, but even Senator Vest was induced to vote in favor of the Warren bill as probably the best compromise which could be secured.

The debate on this bill, as reported in *The Congressional Record*, furnishes some instructive reading. Senator Vest stated, with considerable humiliation, as he said, that he had found after a struggle of twelve years that a persistent and unscrupulous lobby is able to do almost anything it pleases with the public domain, and he expressed the fear that this lobby "would not permit" even the passage of this Senate bill. One would naturally suppose from this that the promoters of this railway scheme comprised a large body of citizens with extensive political and pecuniary influence. On the contrary, it was stated in the debate that this so-called company had never had a meeting; that no books were ever opened for the subscriptions to its capital stock; that it has never made a report; that it has never

built a rod of railway; that under the laws of the state of Montana all its supposed rights were forfeited long ago; and finally, that all these people desire is to obtain a franchise from Congress for the purpose of selling it to the Northern Pacific Railroad Company. Evidence seems to have been submitted to both Houses of Congress which fully justifies these charges against an unscrupulous band of adventurers. Senator Vest declares that they have been able to block all legislation relating to the park simply because they are a compact organization, like an army, persistent, aggressive, untiring and determined to capture this charter and make money by its sale. On the other hand, the friends of the park are few and apathetic, without any co-operation and no influence with either great party, because there are no votes in the Yellowstone either for Republicans or Democrats or anybody else. Senator Sanders, in alluding to these statements of Senator Vest concerning the lobby and its power, added that the Senator from Missouri "had spoken with moderation."

Even if these statements were somewhat exaggerated, it seems to plain people who are not members of Congress that there ought to be sufficient virtue in the House of Representatives, when such facts are brought to the attention of its members, to defeat this Mineral Railway job; and we again call upon all those who are interested in forests and forestry, in natural beauty, and in the good name of the country, to make personal appeal to their Congressmen to vote and work against this Stockdale bill. Senator Warren's bill is not all that is desirable, but certainly it is better than nothing. The twelve-mile strip added to the eastern side of the park is more heavily wooded than the part rejected, and it contains the headwaters of all the streams which run into the Yellowstone River and Lake, besides the sources of the Stinking Water River. It is a misfortune that the portion of the reservation on the south, lying west of the Snake River, is cut off. There are some moose here, although the principal breeding-grounds for great game are east of the Snake River. In our judgment the new states make a mistake in permitting these mountain-regions to pass under private control, but no law which is opposed by the Senators and Representatives of these states can be passed, and the fact that the Warren bill is supported by the Senators from Idaho, Wyoming and Montana gives some encouragement to hope for its passage in the House. The surrender of a few square miles in the north-east corner is no serious loss, since it leaves a good natural boundary for the park and makes an opening for railroads, which will leave no excuse for any further raids for right of way through the park by speculators. Finally, if this Senate bill passes the House, the boundaries of the park will be fixed with some certainty for years to come, at least, and until these boundaries are permanently established the park will be threatened with invasion of one kind or another constantly. As the people learn to appreciate this region, and become familiar with its uses and value, the next change demanded in its boundaries will probably be a further enlargement of its area.

The Management of Cemeteries.

IT seems to be a pretty general belief that in almost every field of human effort demand precedes supply. But in matters where a refined public taste is concerned the supply of good work precedes and creates the demand. For many years the best pictures produced by American artists have not been those which sold the best, and, of course, those which sell the best most truthfully represent the condition of the public taste. Again, our appreciation of the best foreign works of our time has been largely due to dealers who imported the pictures of such men as Corot, Rousseau and Daubigny before we even knew their names, and long before we could understand and properly estimate their art. It is true that in the long run dealers may have profited by this experiment, but the public has profited by it far more, and it is just that we should feel grateful to

them as to unselfish benefactors. What we wish to do now, however, is to call attention to another illustration of this truth which has been suggested by the published report of the *Proceedings of the Convention of the Association of American Cemetery Superintendents*, which was held last autumn in Chicago.

To some eyes there may seem no hint of artistic things or questions in this title. But our readers are aware that we consider the right treatment of the rural cemetery, an institution which is almost peculiar to America, rests on important and interesting artistic principles. And yet it is evident from this report that the greatest obstacle in the way of such treatment is the persistent bad taste of the public. We might suppose that our cemeteries are not more beautiful because it is hard to find people to make them beautiful. But the case is really the reverse of this. Many at least among the persons who are employed to care for them know what aspect they ought to wear, and are eager to give them this aspect; but their employers bar the path. If the bad taste of the committee or trustees who control a cemetery is not to blame, then it is usually the bad taste of the majority of individual lot-owners.

Of course, we should not assert this simply on such statements as that "the superintendents of cemeteries have to bear with many things that they do not like in catering to the public." If no explanations with regard to points of difference were given, we might conclude that the superintendents rather than their patrons need an education in good taste. But the various addresses given at length in this report bear such clear witness to the correctness of the views of prominent cemetery superintendents, and to the conflicting views of their patrons, that one cannot help feeling confident as to the source from which improvement may be expected.

For example, Mr. G. H. Scott, of Rose Hill Cemetery, Chicago, in discussing how large a part nature should play in the cemetery, said: "What may be considered natural in a cemetery? In the first place, grass and trees. There should be an abundance of grass and a sufficiency of trees and shrubs, with as few pathways as possible and no more driveways than are absolutely necessary. A cemetery-lot with mounds or graves not higher than three inches above grade of plain sod, well clipped and trimmed, gives that appearance of neatness, simplicity, quiet and beauty which every such lot should have. The prevailing anxiety on the part of lot-owners to surpass each other in the erection of costly monuments, vaults and stone-work generally, is detrimental to the natural appearance of a cemetery. Another encroachment upon the natural appearance of a cemetery is carpet-bedding. To take the natural and well-trimmed sod from a grave and cover it with a carpet-bedding of plants and flowers, giving it the appearance of a patch-work crazy-quilt, is, to say the least, absurd, and certainly not in keeping with the natural appearance of a cemetery representing the peaceful resting-place of the dead. Not so with plants of wild flowers and hardy herbaceous perennials. They are things of nature. This class of plants are inexpensive, will live over winter, flourish without care, become larger in size and increase in beauty every year, and should be dispersed over the ground so as to give them a natural appearance. A cemetery should be a place for meditation, a place where the living, pleased and satisfied with its natural appearance of peace and quiet, and free from the busy hum of human toil and artistic dazzle, may anticipate the time when they, too, must succumb to the inevitable, not mournfully, but cheerfully. Besides, if cemeteries generally were kept more natural in appearance, their cost of maintenance would be less."

We have taken these sentences out of their context and massed them so as to show, as briefly as possible, Mr. Scott's idea of what the treatment of a rural burial ground should be. And from the speech of Mr. Higgins, of Woodmere Cemetery, Detroit, we may take a few more sentences with a similar purpose. "What," he asks, "are the essentials of a perfect cemetery? Beauty and harmony. Har-

mony, as I here use it, should not be considered as flatness or want of variety, but as a lack of elements of discord which it is difficult to overcome. Thus a small Niagara would not be desirable in the proposed site for a burying-ground, neither beetling cliffs nor wild gorges. Picturesqueness may occasionally be properly sought after in the improvement of parks or private grounds, but is scarcely productive of that air of quiet repose which should be one of the main characteristics of the last resting-place of man. . . . The two crying evils of all cemeteries are our present great ugly headstones and our unsightly grave-mounds. It seems to me, however, that in some cemeteries which are working toward the lawn-plan, they lay too much stress on prettiness and bring with it the puerilities, polish and showiness of highly kept front yards or showy lawns, and that too much money is expended in ornamentation and display. Now, neatness is one thing, display an entirely different thing. I believe that the nearer we keep to nature in our methods of cemetery improvement, the better results we shall obtain and the more economical will be our management of affairs. We must bear in mind that cemeteries are designed for burying-places for the poor as well as for the rich, and that extravagance in ornamentation or wasteful methods of care defeat the very purpose for which they were intended."

Surely these ideas are sound. They are the truly artistic because the truly fitting principles in accordance with which rural burial grounds should be designed and maintained. It is pleasant to know that persons holding executive positions in our cemeteries entertain such ideas, and we should be glad to know that they were less frequently hindered from acting upon them by their employers.

The Cork Oak.

A SUBSCRIBER in California has asked us for information with regard to the cultivation of the Cork Oak, and being unable to find anything satisfactory on the subject published in works of European silviculture, we addressed the question to our learned correspondent, Monsieur Charles Naudin, of Antibes, in France, who sends us the following reply:

The Cork Oak, like the Chestnut, is only found on sandy soil, and grows in forests in Provence, in Roussillon, Corsica and Algeria. It is not cultivated, although owners of sandy soil sometimes sow the acorns on ground from which forests of this tree have been removed, but their operations are confined to planting the acorns, and nothing is done to the trees until they are old enough to produce a crop of bark. It is believed, however, that it will be a profitable operation to pay some attention to the young plantations, especially to clear them of other trees and shrubs and to prune the trees in order to hasten the development of their trunks. It is customary to find Cork Oaks mixed with other trees—Pines, Ilex, Chestnuts, etc.

From the classical *Quercus suber* the botanist Jacques Gay separated as a distinct species, under the name of *Q. occidentalis*, a variety with very thick corky bark peculiar to south-western France outside of the Mediterranean basin, which he distinguished from the ancient *Q. suber* by the biennial ripening of the acorns, but this character is so little constant that botanists have not considered this form specifically distinct, although, and this is worth noting, it is much hardier than the Mediterranean form. Fifty or sixty years ago, Monsieur Trochu, father of the General of that name, made plantations of the two Cork Oaks on Belle Isle, on the coast of Brittany, in an oceanic climate. The Oak of the south-west flourished here while those from the shores of the Mediterranean all perished. This seems to indicate a specific difference, or at least a physiological difference. I do not doubt that the Mediterranean Cork Oak will succeed in California if it is planted in sandy soil; at any rate, it would be interesting to try there the two species, or the two varieties, in order to judge by comparison which is the more valuable.

Speaking of Oaks, an old forest-officer, Monsieur Bouguet de la Grye, tells me that *Q. Banisteri* (*Q. ilicifolia*) of the southern United States produces great quantities of acorns. If it really possesses this quality it should be introduced into Algiers, where the acorns would serve as food for pigs.

The Morningside Plateau, New York.

MUCH has been said of late about Morningside Park in this city and the various large buildings which it is proposed to erect in its neighborhood. But comparatively few persons, even in New York, understand what a great feature of New York these buildings and their surroundings may eventually become. The site and character of Morningside Park itself are pretty well known. The tract where the proposed buildings will stand is called Morningside Plateau, and extends from Morningside Avenue at the east, where it forms a high bluff overlooking the park, with a distant view of Long Island and the Sound, to Riverside Drive, which follows the brow of lofty banks of the Hudson. This commanding plateau extends north and south for nearly a mile and a half and varies in elevation from 110 to about 145 feet above tide-water level, and the only buildings which now stand upon it, with the exception of scattered cottages—relics of the time when the city was far away—are the Leak and Watts Orphan Asylum, the old De Peyster house, once a noted country-seat, and the Bloomingdale Insane Asylum. The presence of this last-named institution had, for more than a generation, deterred people from purchasing land in the neighborhood for private residences, and it was owing to the exertions of local property-owners, intent upon redeeming their possessions and bringing them into a profitable market, that the rugged tract along its eastern skirts was set apart for public use and transformed into a pleasure-ground.

Then, several years later, the ground owned by the Orphan Asylum was purchased by the trustees of the proposed Protestant Episcopal Cathedral, and at about the same time the property-owners, determined to get rid of the Insane Asylum, induced the Legislature to pass a bill opening One Hundred and Sixteenth Street, through to the river. This action induced the governors of the New York Hospital, which owns the Insane Asylum, to decide upon its removal to land purchased long ago at White Plains, and to offer its present site at public sale in lots suitable for private building. But then the trustees of Columbia College obtained an option on the entire property, and a bill, which had been introduced into the Legislature to provide for the cutting of another cross street through the plateau, was defeated in order that the college might have an undisturbed site of suitable extent. All indications point to the fact that work on the cathedral will shortly be begun; and there is likewise no doubt that Columbia College will soon raise the money needful to purchase the land now reserved for it and erect a fine group of buildings.

The Cathedral Parkway will be a wide avenue crossing the southern end of this plateau on the line of the northern boundary of Central Park—that is, at One Hundred and Tenth Street—and from this point for the distance of three city blocks is the site of the future cathedral, while the new site for St. Luke's Hospital adjoins it on the north. A little farther north and west, between One Hundred and Sixteenth and One Hundred and Twentieth Streets, is the proposed site for Columbia College, and immediately north of this again, extending to the line of One Hundred and Twenty-second Street, is the proposed site for the College for Training Teachers. The space between the Boulevard and Riverside Drive is narrow, and, as a rule, somewhat sloping; so there will be a magnificent view from all these structures that are to be, while, if their architecture is what we may expect, they will vastly increase the attraction of the eastward outlook from the beautiful drive, forming, for a great part of its length, a background of stately buildings lifted above those on its immediate edge. Nothing, therefore, could be more fortunate for the city than this agreement between several very wealthy corporations to erect their buildings in this place; and, of course, the profit will not simply be the presence of these buildings themselves. Once the Insane Asylum is removed, the old prejudice against the plateau as a place of residence will vanish, and the existence of the ecclesiastical and collegiate groups will, indeed, bring it into the very highest esteem for this purpose. The value of any land within the borders of New York is and always will be too great for us to cherish the hope that building-sites, even in this locality, will be laid out on the generous scale which has been found practicable in other cities, especially in the west, and which adds so greatly to their dignity, beauty and individuality.

We cannot expect, even in the neighborhood of the grounds of the cathedral and of Columbia College, to find private houses surrounded by lawns and gardens of any great extent. But many recently erected buildings along Riverside Drive prove that it is possible for the wealthy, even in New York, to build houses which do not actually touch each other, and even

this much isolation gives the architect a great opportunity to improve upon the average New York house and secure both a greater degree of architectural dignity and a fuller expression of what we may call domestic personality. All the architects who have built along the drive have not used this opportunity well. Sometimes an effect of rampant ostentation has been secured instead of dignity and the home-like look which every private house, however large and costly, ought to wear; and instead of an artistic design we see one which is no more than artfully elaborate, or just as artfully and inappropriately rugged and rude. But as the years go on we shall learn more and more what true architectural elegance and true architectural simplicity mean. And as it will be a good many years before Morningside Plateau is covered with buildings, we need not doubt that it will eventually be a district in which New Yorkers can feel genuine pride.

It is interesting to know that when, about the year 1815, the New York Hospital found its city building too crowded for the accommodation of its insane patients and accordingly purchased the "Bloomingdale Farm," the price paid was \$4,000, although this farm was of greater extent than the property now owned by the institution, and that two years ago, when a hundred building-lots of ordinary size were cut off from this and sold, some of them individually brought \$4,000 in spite of the fact that they lay on still unopened streets. With the recent promise of the advent of the cathedral and the college, values have vastly increased again. Lots in the neighborhood of the asylum property could now be sold at from \$15,000 to \$20,000 each, and few owners are willing to sell at all.

New or Little-known Plants.

Viburnum cotinifolium.

THIS is a handsome shrub of Cashmere and the north-west Himalayas, where it is common at elevations of from four to seven thousand feet above the sea-level, and a near relative of the common Wayfaring-tree of Europe, *Viburnum Lantana*, from which it only differs in the dentation of the leaves and the larger limb of the corolla. It is a vigorous plant with stout stems, which attain a height of five to ten feet. The leaves are ovate or elliptical, obtuse or subacute at the apex, rounded, truncate or subcordate at the base, minutely crenulately serrate, stellate-woolly on the under surface when young like the young shoots, but ultimately nearly glabrous except on the lower side of the nerves, reticulate-rugose, dark green above, pale below, and about three inches long by two inches broad. The flowers, which open here by the end of May, are produced in dense thick-branched hirsute corymbs two or three inches across and generally terminal. The calyx is narrowly obconic, glabrous, with a short limb, the triangular lobes usually tipped with red. The corolla is white tinged with pink, shortly campanulate, the limb an eighth of an inch across when expanded, the spreading lobes as long as the tube. The drupe is oblong, compressed, a quarter of an inch long, bright red at first but ultimately nearly black; the seeds two-grooved on the back, and ventrally subconcave and three-grooved.

Viburnum cotinifolium (see page 245) was raised in the Arnold Arboretum, in 1881, from seed sent from the Botanic Garden of St. Petersburg and has proved hardy here with careful protection, although plants derived from other sources have not been able to bear the winter climate of eastern Massachusetts.

The size and the color of the flowers make it a handsomer plant than *V. Lantana*, which is, however, more vigorous and hardy here, and which will probably never be supplanted for general cultivation in the northern states by its Himalayan relative. C. S. S.

New Orchids.

DENDROBIUM BARBATULO-CHLOROPS, Rolfe.—A natural hybrid between *Dendrobium barbatulum* and *D. chlorops*, which flowered in the collection of Major-General E. S. Berkeley, of Southampton. It has the white flowers and general shape of the former, with the crest and light green side lobes of the lip of the latter. Both the species are natives

of the Deccan Peninsula, and grow together in quantity. Its appearance is therefore very interesting.—*Gardeners' Chronicle*, March 5th, p. 298.

PELEXIA TRAVASSOSII, Rolfe.—An elegant species, one of the prettiest of the genus, with white flowers lined with brownish red. The leaves are olive-green, with silvery nerves and a few white spots. It was sent from Brazil by Senor Travassos, and flowered in the Kew collection and elsewhere.—*Gardeners' Chronicle*, March 12th, p. 330.

CYPRIPEDIUM × BRYSA, Veitch.—A secondary hybrid raised from C. × Sedeni candidulum crossed with the pollen of C. Boissierianum, and said to be like a large form of the former, with a greenish tinge. Messrs. James Veitch & Sons, of Chelsea, received an award of merit from the Royal Horticultural Society for it on March 8th last.—*Gardeners' Chronicle*, March 12th, pp. 343, 344.

CYPRIPEDIUM × IANTHE, Veitch.—A secondary hybrid raised in the establishment of Messrs. James Veitch & Sons, of Chelsea, from C. × Harrisianum crossed with the pollen of C. venustum. It received an award of merit from the Royal Horticultural Society on March 8th last.—*Gardeners' Chronicle*, March 12th, pp. 343, 344.

DENDROBIUM DENSIFLORUM, var. CLAVATUM, Rolfe.—A distinct geographical variety from the Shan States, remarkable for its very clavate pseudo-bulbs, which taper to a very slender base. The flowers are white, with an orange-yellow lip. Its peculiarity may be due to the comparative dryness of the region it inhabits. It was imported by Messrs. F. Sander & Co., of St. Albans.—*Gardeners' Chronicle*, March 26th, p. 394.

CYPRIPEDIUM CALCEOLUS × MACRANTHOS, Barbey.—A natural hybrid between C. Calceolus and C. macranthos, imported from the Birch-forests of western Siberia, where the two species grow intermixed. It flowered with Monsieur Barbey at Valleyres. It is precisely intermediate in character, as the flowers are smaller and paler in color than C. macranthos, with all the organs of the flower modified in the direction of the other parent. It is specially interesting as the first natural hybrid in the genus.—*Gardeners' Chronicle*, March 26th, p. 394.

PELEXIA WENDLANDIANA, Kranzlin.—A species, remarkable for its long filiform sepals, which appeared in the collection of Monsieur Wendland at Herrenhausen. It bears a raceme of about twenty greenish brown flowers, with a white lip.—*Gardeners' Chronicle*, April 2d, p. 426.

CYPRIPEDIUM × CLEOPATRA, O'Brien.—A secondary hybrid raised in the collection of C. Winn, Esq., of Birmingham, from C. Hookeræ crossed with the pollen of C. × oenanthum superbum. It has the general characters of the mother plant, but modified in the direction of the other parent, especially in the purplish crimson coloring of the upper half of the dorsal sepal and the outer halves of the petals.—*Gardeners' Chronicle*, April 9th, p. 458.

CALANTHE VESTITA, var. FOURNIERI, Rolfe.—A well-marked geographical variety, imported from Borneo by Monsieur Fournier, of Marseilles. The flowers, which vary from pure white and blush to deep rose-pink, are smaller than those of the type, while the pseudo-bulbs are constructed in the middle, like those of the variety Turneri. It recently flowered with Messrs. F. Sander & Co., of St. Albans.—*Gardeners' Chronicle*, April 16th, p. 488.

CYPRIPEDIUM × LAWREBELLUM.—A hybrid raised in the collection of Sir Trevor Lawrence, Bart., M. P., from C. Lawrenceanum crossed with the pollen of C. bellatulum. The flower is intermediate in shape, the color rich rosy crimson, with a tinge of green at the base of the sepals and petals, a pure white margin and some purple-brown lines on the upper sepal, and some chocolate spots on the petals. It was awarded a first-class certificate by the Royal Horticultural Society on April 12th last.—*Gardeners' Chronicle*, April 16th, pp. 502, 503; April 30th, pp. 560, 561, fig. 82.

DENDROBIUM × ADRASTEIA, Veitch.—A hybrid raised from D. Pierardii crossed with the pollen of D. superbum. The sepals and petals are pale pink and the lip primrose. It was raised by Messrs. James Veitch & Sons, of Chelsea,

and exhibited at a meeting of the Royal Horticultural Society on April 12th last.—*Gardeners' Chronicle*, April 16th, p. 503.

LÆLIO-CATTLEYA MARRIOTTIANA.—A hybrid raised in the collection of Sir William Marriott, of Blandford, between Lælia flava and Cattleya Skinneri. It bears upright spikes of yellowish pink flowers, the younger ones having a brownish tint. It received an award of merit from the Royal Horticultural Society on April 12th last.—*Gardeners' Chronicle*, April 16th, p. 503.

Kew.

R. A. Rolfe.

Begonia Gloire de Lorraine.

THIS is the name given to a new winter-flowering Begonia raised by the Messrs. Lemoine from B. Socotrana, as the seed-parent, and B. Dregei, as the pollen-parent. The seeds, which ripened in February, 1891, were sown at once and came up in the spring. The young seedlings began to flower about the middle of November and are still in bloom. Although B. Socotrana is bulbiferous and B. Dregei tuberous, the hybrid forms neither tubers nor bulbets, but the base of the stem is throwing out many shoots, which will insure the rapid multiplication of the plant.

The leaves are rather small, nearly regular, of a clear green; the flowers almost exclusively male, with four petals, are large, and borne in broad panicles, covering the whole superior part of the plant. They are of a fresh rose color, and, being not deciduous, remain a very long time on the plant. This novelty (see page 247) was exhibited in February before the National Horticultural Society of France, in Paris, and was awarded a first-class certificate with a special mention, and it is highly commended in the French horticultural journals. It is probable that older and stronger plants will make admirable specimens.

Grape "Proligère de Varna."

THIS Grape already forms the larger part of some of the vineyards about Varna, France. It is native to the shores of the Black Sea, and appears to be quite variable. There are already several distinct varieties grown in the vineyards of Varna, some of them being excellent for table use. The grape makes a red wine of fairly good quality, but it could undoubtedly be much improved. The most interesting feature of the Grape is its productiveness, and it is this which suggested the name Proligère de Varna. Instead of bearing only two or three bunches upon every shoot, as most Grapes do, it has from four to eight. One might almost say that every tendril is transformed into a grape-cluster.

The plant, as growing in the vineyards, may be briefly described as follows: The canes are very vigorous and attain a length of several metres; they are commonly cut back. The wood is yellowish red, downy; internodes of unequal lengths, longitudinally grooved; buds large, white, pubescent. Petioles robust, cylindrical, tomentose, reddish brown, and from seven to eight-centimetres long. Leaves orbicular, thirteen to fifteen centimetres in diameter, the central sinuses of the lower ones oval and almost closed, those of the upper leaves being considerably larger, dentate, the teeth short, strong, mucronate; the lower surface pubescent, veins prominent; upper surface glabrous, but not glossy, showing a net-work of fine non-protruding veins. Clusters three to eight upon each shoot; peduncles green and red, short, very strong. The lower clusters are ten to fifteen centimetres long and quite compact; the upper ones are smaller, more open, and sometimes bear a tendril. Pedicels short (four or five millimetres), rugose, the inner extremity slightly enlarged. Berries almost spherical or slightly oblong, the longitudinal diameter being sixteen millimetres, the transverse fifteen millimetres; color a uniform black; skin moderately thick and rich in tannin; flesh deep grayish red, sweet and piquant to the taste. Seeds greenish brown, rounded, not rugose.—*Ed. André, in Revue Horticole.*

[No doubt this Grape would flourish in California, and it would be worth testing in the southern Atlantic states. Even if it is nothing more than a variety of *Vitis vinifera*, it is sufficiently distinct to suggest to hybridizers the idea of crossing it upon some of our native species.—*Ed.*]

Foreign Correspondence.

Forest Hill Nurseries.

THE nurseries of the well-known firm of Messrs. J. Laing & Sons are about eight miles from St. Paul's Cathedral, and two from the Crystal Palace at Sydenham. They were founded by the veteran John Laing about forty years ago, and they are now famed for tuberous Begonias, Gloxinias and Caladiums, which have been a speciality with

long by fourteen feet in width, low, span-roofed, with a low fibre-bed on one side and a cinder-bed on the other side of the path. The sun shone full in upon the plants, and the temperature was that of a moist stove. Laing's Begonias are always first-rate, but those I saw the other day were certainly far finer than any I have ever seen. One house contained single-flowered varieties. They were in nine-inch pots, planted in yellow loam, manure and plenty of sand, and they had been started in January. Many of the plants were a yard across, with leaves often a foot long and

Fig. 47.—*Viburnum cotinifolium*.—See page 243.

Messrs. Laing for many years. The tuberous-rooted Begonias are grown there better and in larger quantities than anywhere in England. Mr. John Laing, indeed, may be called the originator of the Begonia cult, as he was one of the first to set to work in earnest to breed improvement into these plants, and he has done far more to make the Tuberous Begonia what it now is than any other breeder, professional or amateur. I was invited last week by Mr. Laing to inspect his first batch of Begonias in flower. These were in two large houses, each one hundred feet

half as broad, very thick and succulent, pictures even without the flowers, and the flowers were simply marvelous, both in regard to size and colors. Flowers four inches across were numerous; there were also many kinds which, while having only medium-sized blooms, were elegant in form. The florists' ideal flower, round and flat as a saucer, was represented, too, and was pointed out with pride by Mr. Laing, who remarked that, although they were not every one's choice, yet the florist had to be considered, and that it was only when aiming for his ideal that good things

of all kinds were obtained. All these magnificent plants, robust in habit, large in flower and rich in shades of color, had been selected from the fields of seedlings which in this nursery are raised every year and planted outside in June. The best of them are named, but, says Mr. Laing, "we get on so fast and improve so every year that the choicest of last year are only second-rate compared with those of this."

In the other house all the plants were double-flowered, and these were even more astonishing than the single-flowered ones. "We are aiming now to get erect-flowered double varieties. Hitherto they have had the drawback of being too weak in the stalk to bear the weight of the heavy double flowers, so that they looked 'floppy.' But, see," said Mr. Laing, "we are getting on." And sure enough there were plants, large and full of flower, all holding their big Carnation-shaped blooms perfectly upright without the support of stake or tie of any kind. "We shall in time, if we care to, get the stalks so short and stout that the flowers will all hold up their heads like *Cinerarias*." *Begonias* have proved exceptionally plastic in the breeders' hands. It is scarcely credible among outsiders that the best of the seedlings we now possess are the progeny of several Andean species of *Begonia* which were almost unknown twenty years ago, and the flowers of which, compared with the huge blooms of some of Mr. Laing's latest seedlings, are as a Wellington apple is to a crab.

The named kinds which I made special note of were Princess May, a pure white, double, perfect in form, large and full; "the best white yet," Mr. Laing said. It has just returned from an exhibition at Regent's Park, where it had been awarded a first-class certificate. Lady Theodore Guest, another big double-flowered seedling, was remarkable for its wavy petals, colored buff, tinged with salmon. Mrs. Regnart, with full chrome-yellow flowers as large as a child's fist, had also received a certificate.

The best of the new erect-flowered double sorts was one named Baron Schröder. The blooms were fully three inches in diameter, very double, perfectly erect and colored a rich orange-scarlet. Perfection was another plant with stem erect and a large double flower colored rosy scarlet. Baroness Burdett Coutts had semi-erect flowers, large, wavy, and colored a soft pale salmon. Another pretty variety was named Mrs. Coomber; it had Picotee-like flowers, colored creamy white with a rosy edge.

Mr. Laing says he has a great display of *Begonias* from April till October, and that he could have it all the year round with a little management. The two houses described were the "show-rooms" merely; the "work-shops" revealed how the thing was done. Long low houses and frames were filled, or being filled, with boxes of recently pricked off seedlings, a dozen or so young lads, fresh from the board-schoolmaster, being seated round a big bench pricking the little plants off. The boxes used were fifteen inches by nine and two inches deep. Forty plants were put into each box, of which ten thousand at least would be filled this year. The frames were placed upon hot-beds of manure, with a thick layer of spent hops spread over the top of the manure. "Nothing like hops to keep down the fly and make the seedlings shoot along," said Mr. Laing. "What becomes of them all?" I asked. "Why, bless you," said he, "they don't stay with us long; we can easily find customers for all we grow."

The work of selection and crossing, which Mr. Laing does himself, is conducted in the houses in which only specially good varieties are grown, so that in the event of stray pollination not much harm is done. Mr. Laing informed me that the very best kinds are obtained from seeds, and that, except in very few cases, it is scarcely worth while to propagate the plants from cuttings.

The *Caladiums* are second only in interest to the *Begonias*. Some of the varieties are gorgeous in color, and the leaves as large almost as umbrellas. Messrs. Laing grow *Caladiums* better than any one in London, their groups at the great exhibitions being far ahead of every other exhibit of the same kind. I noted down the

best, to my taste, of all the *Caladiums* I saw there among the hundreds of named varieties grown. Mrs. Harry Veitch has large broad leaves, blush-white, with the midrib and larger veins colored rich crimson; John Laing has equally large leaves colored bright rose-red, with a creamy white border; *Reine de Danemark* is colored delicate rose with carmine veins, and netted all over with green; *Maria Mitjana* is almost wholly rich rose; *Madame Marchand* has grand leaves, colored rosy carmine, margined with dark green; *Aurore Boreale* is deep red, lined with carmine and blotched with a peculiar metallic green; *Chactas* has large deep red leaves with green borders; *Raymond Lemoigner* has a creamy white centre, a rich red outer part, very large leaves, and is a magnificent variety: P. S. Williams is deep rose, with carmine-red veins; *Candidum* has white leaves, with very conspicuous green ribs; *Bellone* is rosy colored in the centre, red-maroon toward the margin, and tinged with brown; *Leopold Robert* has a beautiful leaf, colored blush-white, with a rich green border and carmine-red ribs; *Gaspard Crayer* has a red centre, with a broad border of deep green blotched with red; *Ornatum* has a grass-green ground, with carmine ribs and crimson veins; *Charlemagne* has large rosy red leaves, with dark red veins; *Madame M. Scheffer* has large white leaves, with rosy ribs, veins and margin. These sixteen varieties are remarkable for the large size of their leaves, their exceptionally brilliant colors and delicate tracery. They are not all Mr. Laing's first favorites, but they are what I would select for myself. The cultivation of these plants is not at all difficult, and yet there are very few growers who can produce anything like the grand specimens which come from Forest Hill. Here are the details of culture for them as recommended and practiced by Messrs. Laing:

Caladiums are easily managed. They require a good moist heat to develop their beauties, and a fair amount of shading at the commencement of the season, as in some instances the texture of the leaf is thin, and, unless carefully shaded from the sun, the glass is apt to burn the foliage, and thus permanently disfigure it; but avoid too heavy shading and too much heat, as this encourages flimsiness and thin foliage. The bulbs should be potted when growth commences in spring, and a compost of two parts peat, one part turfy loam, one part silver sand, and plenty of drainage, and placed in a brisk bottom-heat, with a moist temperature of seventy degrees, and, with frequent potting, they will soon make large plants. Care should be taken not to water very liberally until the pots get well filled with roots, and then, if required, apply liquid manure regularly. Syringing is beneficial.

For ordinary purposes, bottom-heat to start them is quite unnecessary, but a light position near the glass is of more importance, and is at all times essential. The plants in summer, before being removed to cool houses, should be hardened for a week in a less warm house than the stove, otherwise much of their beauty will go before they get used to the change.

When their beauty begins to fade, gradually dry them off by giving them less water, but on no account should the soil be dust-dry all the winter, or when starting-time arrives the bulbs may be found to have disappeared from the "dry-rot" disease.

The Forest Hill Nurseries are not devoted only to a few things, for there is also a good collection of Orchids, stove and greenhouse plants and fruit of all kinds.

The Loss of Vigor in Varieties of Strawberries.

THE marked decline of the Wilson Strawberry during recent years is well known to all who have been familiar with this fruit as grown in this country during the last two decades. Yet a few growers, among whom may be named Mr. J. M. Smith, of Green Bay, Wisconsin, continue to have excellent success with this time-honored variety. Indeed, Mr. Smith claims that no recent variety among many he has tested fully equals the Wilson in yield. He has long ascribed his success with the Wilson to the fact that he invariably takes his plants for setting from beds set the preceding spring, and which have not borne a crop of fruit.

Certain experiments that I have been making lead me to

believe that Mr. Smith is correct in this reasoning. The results of these experiments seem to show that the so-called "spot disease" or blight of the strawberry, caused by the fungus *Ramularia Tulasnei*, may produce an enfeebled condition of the plant from which it does not rally for at least several generations. It is well known that the Wilson Strawberry is very subject to this disease, but that plantations do not often suffer much from it until the year after planting.

In the spring of 1889 Mr. Smith kindly sent me fifty plants of what he thought his most vigorous Wilson strain. These were divided into two lots of twenty-five plants each, and

favorably located, hence I can ascribe no other cause for the failure of this bed than the disease from which it has suffered.

In order to test the validity of Mr. Smith's theory, as noted above, I have been careful to plant each spring a new bed of young plants taken from the bed set the previous spring, and which consequently has not borne a crop. With these I have been comparing other beds formed of young plants from the diseased bed mentioned above, and also from other beds that, while not especially diseased, had borne at least one crop of fruit. I have endeavored to secure a comparative record of yields from these plantings, but as the exact number of healthy

Fig. 48.—Pagonia Gloire de Lorraine.—See page 244.

planted in two small beds about four rods apart. Both beds did well during the first summer, and yielded a good crop of fruit in 1890. But after the fruiting season, one of these beds was badly affected with blight, while the other, from some unknown cause, was nearly or quite exempt from it, and the same was true in the summer of 1891, the same bed being free from blight both seasons. The result is that but forty-four plants in the diseased bed have survived the past winter, while 234 plants have survived in the other bed. If there is any difference in the environment of the two beds, the one that has suffered so badly from blight would seem to be the more

plants in the different beds was not noted at the time the fruit was gathered, the figures based on crop alone might be very misleading. It will be more just to compare the vigor of the different plantings by noting the number of surviving plants at the present time. I may add, however, that the differences in yield, so far as ascertained, are quite as conspicuous as are those of plant production.

Last spring a bed of sixty-five young plants was made, the plants being taken from a bed set the previous spring, and which had been set in the spring of 1890 from the healthy bed grown from Mr. Smith's plants set in 1889. In other words, the

ancestors of these sixty-five plants had been free from disease and had not borne a crop, at least since 1888, and, as Mr. Smith affirmed, for many years previous. This bed now contains 332 strong plants, besides some others that have suffered from the winter, or a fraction over five and one-tenth plants to each one set last spring. It should be remarked here that August and September of last season were the driest I have ever known, which explains the meagre growth of plants. Twenty-six young plants from the blighted bed above mentioned were set last spring in two short rows adjoining the sixty-five plants just mentioned. The vigor of this blighted bed had become so much reduced that a larger number of young plants could not be obtained; these twenty-six plants are, therefore, from parents blighted severely for two generations, and yielding a crop of fruit the summer previous. But forty-three plants have survived the winter from this bed, or a little less than one and seven-tenths plants to each one set last spring.

Another small bed of thirty-nine young plants was set last spring adjoining the one just mentioned. For this the plants were taken from a bed that was set in 1889, and hence had borne a crop of fruit but which had not suffered much from blight. In this bed a fraction less than four plants have survived the winter for each plant set. Recapitulating then, we have:

Plants with ancestry free from disease, and not weakened by bearing, five and one-tenth surviving plants for each plant set.

Plants with ancestors suffering from disease two preceding generations, and further weakened by bearing, one and seven-tenths surviving plants for each plant set.

Plants with ancestry nearly free from disease, but having borne one crop of fruit, four surviving plants for each plant set.

It may be added that the above three lots of plants were all set on the same day and have received exactly the same treatment.

It will hardly be denied that the differences of vigor manifested in the above plantings are greater than we should usually expect from different varieties of the Strawberry similarly treated. The lesson seems clear enough. It is unwise to plant a new Strawberry-bed from a plantation that has suffered from the attack of *Ramularia*. The young plants from such a bed, whether they develop the disease or not, are reduced in vigor, and are not likely to prove satisfactory. I ascribe Mr. Smith's fine success with the Wilson Strawberry more to his having always grown his plants from parents that were free from disease, than from the fact that they had not been permitted to bear.

It seems not improbable that in fruits like the Strawberry better results may be gained through methods which aim at promoting the vigor of the varieties we already have, than in continuing the production of new seedlings, the method of improvement usually adopted.

Wisconsin Experiment Station.

E. S. Goff.

Cultivation for Health.

THE notes from Colonel Pearson in a late number of GARDEN AND FOREST touch a question of importance in several directions. He planted Potatoes on poor soil, where they made but feeble growth, and near them he planted the same variety of Potatoes on soil enriched with nitrogenous manures; and the weak plants on the poor soil were attacked by insects and devoured before the others were touched—indeed, the strong plants were practically untouched. The same consequence followed when the blight appeared. The truth illustrated by this instance seems to be that insects and fungi, to a considerable extent, are in the habit of attacking and destroying vegetation already enfeebled or dying. My own illustration of the same truth occurred last year in a field where, of a dozen sorts, one variety stood green and untouched by beetles while every other kind was badly devoured. This was not owing to soil or fertilizers, for the same treatment was given to all sorts; and this exception was surrounded by others that were eaten. The two rows stood up as green as June in the middle of frost. What was the reason of this? My own solution is, that the exempted plants were of a new variety, a sport of Morning Star, that is exceedingly vigorous and does not blossom till September, nor mature till late November; in fact, it needs a season longer than I can give it. Planted together on the same date, the other sorts came up quickly and received a check from early frost; the tops were enfeebled. This new kind did not start up until after the frosts, and grew stoutly and steadily. The beetles attacked the feeble plants and did much mischief, just as they did in New Jersey.

The lesson, therefore, is to get a vigorous growth which has a resistive power against insects. Examine your house plants; if the aphid appears you may, as a rule, look for water-soaked roots or pot-bound roots or other cause of enfeebled growth. The bugs appear as nature's provision to turn sickly and sickening vegetable matter into non-deleterious animal matter. On a wider scale we may look on the bugs and worms in many cases as scavengers in our fields for our own good.

Healthy growth should be the ambition of cultivators. I do not mean to say that those destroyers that prefer unwholesome vegetation will not go farther and spread devastation over comparatively healthy foliage; but I was astounded at the appearance of the Potato I have mentioned. Plant a Cherry-tree in a dark and shady spot, and it will be loaded with the black aphid; and your Viburnums will, if set in shade, be covered with green aphides; while the same trees, if in open sunny spaces, are comparatively free. So far as our Potatoes are concerned the tendency of our system of cultivation is to enfeeble the plant. We plant small potatoes or small pieces which do not nourish the stalk well to begin with, and do not contribute to the health of the plant. The application of Paris green is also enfeebling. The growth in poor soils without food, as Mr. Pearson suggests, is in the same line of deterioration. Of course, there are insect hordes and plant pestilences which sweep everything before them, but the value of vigor as a protection against the attacks of disease and of insects ought to be more thoroughly appreciated.

E. P. Powell.

Plum-flower Blight.

THERE is complaint that the flowers of Plum-trees are blighting badly. An examination of specimens thus affected shows that the blossoms, and particularly the flower-stalks, are brown instead of green, as they should be, and are covered with a gray mould. This mould is a fungus (*Monilia fructigena*) that frequently appears upon Plums, Cherries and Peaches later in the season, and most commonly when the fruit begins to ripen. The fungus is a rampant grower and will destroy a ripening fruit in a few hours, coating the decayed substance with a felt-like layer of spores.

In the case in hand the *Monilia* has come early while the crop is in the blossom state, and upon some trees no fruit will set because every flower is already mouldy, and all the flower-stalks are dead and covered with the spores of the fungus. Nothing can be done to save the fruit upon such trees, but it should be borne in mind that they are nurseries of a fungus the spores of which will find their way to other Plum-trees later in the season and induce a destructive decay. They may likewise seriously diminish the crop of the Cherry and Peach orchard.

Here is, therefore, an instance when spraying is important, not that the sprayed tree will bear fruit, but that the fungicide may save the fruit of other and more fortunate trees. Spraying one tree to save the crop upon another is practicable—it is, in fact, taking hold of the long end of the lever and using the ounce of prevention that often outweighs the ton of attempted cure.

Byron D. Halsted.

Aquilegia Stuartii.

THIS Columbine has been described as the most beautiful of all cultivated kinds, and as the plants are just flowering with us for the first time from seed, I wish to add my testimony to its excellence. Its parents are said to be *Aquilegia cœrulea*, a North American species, and *A. glandulosa*, which is of Siberian origin. The plant shows plainly by its very dwarf foliage the influence of *A. glandulosa*, but the flower-stems are longer than those of that species, although not more than eighteen inches high, while the flowers are large in proportion, being four inches across. The petals are dark blue and the centre white, so that in general appearance the flowers resemble a good variety of *A. cœrulea*, but the spurs are shorter. Taken altogether, *A. Stuartii* is an improvement on its parents, both of which have a rather doubtful reputation as good border-plants. *A. cœrulea* has a provoking way of dying after flowering, and sometimes before, and *A. glandulosa* rarely does well in gardens unless raised from seed and set out where it is to remain. Stuart's Columbine is probably the only authentic hybrid from *A. glandulosa*, the seeds of which differ from all others, being of a dull opaque black, and the seeds of *A. Stuartii* are similar, while the seeds of other Columbines are of a bright shining black. *A. Stuartii*, we believe, was raised in Scotland, and was first distributed by Mr. Wm. Thompson, of Ipswich, England.

It should be remarked, also, that this *Aquilegia* is very early in flower; there was no other species in bloom when it first opened, not even the native *A. Canadensis*, and now all other varieties will be sacrificed as they flower to be sure that seeds can be saved true. In this way only can *Aquilegias* be perpetuated by seed.

Notes on Forsythias.

THE Forsythias have blossomed with their usual profusion again this season, their bright yellow flowers giving us pleasure during nearly one-tenth of the year, for the earliest blossoms may be found by the middle of April, or soon afterward, and in a cool spring they will be preserved and continued for six weeks. Naturally we find the first flowers on the stems which trail on the ground, because there the buds first feel the effects of the sun on warm spring days.

The Forsythias bring up the much-disputed and never-ending question as to the correct names of the species or varieties, and there seems to be as much or more uncertainty to-day as to what form we shall get from a nursery, under any particular name, as there was ten years ago. All the variations may be divided into the two well-known characteristic forms—one a very long-branched, trailing, slender, pendulous shrub, the other with shorter, stouter branches, which are always erect, or only partially drooping. In certain situations we find plants of the first kind with less free-growing, vine-like, pendulous shoots, but this peculiarity appears to result from local conditions, and is not characteristic of the race. This pendulous species, which we know as *Forsythia suspensa*, is perhaps the most beautiful in flower because the most graceful when growing in a large clump or mass. In its best form it may be trained high up on a wall or allowed to grow naturally. In the latter case the long shoots grow until they bend over and the tips touch the ground, when they will form independent roots if the soil gives the least encouragement. In this way a single bush may eventually spread over a large area and form a mass composed of many individuals, but all from one parent—a sort of Walking Forsythia it might be called if compared with the habit of the so-called Walking Fern. One of the best botanical characters of the plant is that it has trifoliolate leaves, but these are often accompanied by single leaves on the same branch. In fact, simple leaves are most common on less vigorous shoots, while trifoliolate, deeply-toothed leaves are characteristic of more vigorous growths. They are usually ovate in outline.

The Forsythia of our gardens, which is the direct opposite of *F. suspensa* in habit of growth, is *F. viridissima*, with stiff, erect, unbending, bright green, four-angled stems, which apparently do not grow more than seven or eight feet in height, the average being somewhat less. Its leaves are never trifoliolate, but are simple, narrow, lanceolate, pointed, and evenly, but finely, serrated. An authority has described them as entire, but this is evidently a mistake. In this, and all the others, however, it will be noticed that the first lowest or outside leaves are smaller than the others, and are entire or without teeth on the margins. But these first leaves are mainly true bud-scales or coverings, of which there are two or three pairs, the inner ones having a distinctly accrescent character, growing into serviceable leaves. The tube of the corolla of *F. viridissima* is small, the petals narrow and of a deeper greenish yellow color than any other form, and the flower-stalks are shorter and with a decided curve downward. The blossoms do not appear here until fully a week later than any others. Between this stiff little species and the more graceful trailing *F. suspensa* we have the intermediate form or forms which give botanists some trouble to properly classify. *F. suspensa* is apparently also known as *F. Fortunei* in Europe, but the plant we are likely to get under this name in America is intermediate in habit between the two species mentioned, being of larger growth than *F. viridissima*, but without the slender trailing habit of the other, and without any trace of trifoliolate leaves.

The flowers, as a mass, usually have a deeper yellow effect than those of the trailing form, and they are individually not to be distinguished from them in size. The leaves are broader and shorter than those of *F. viridissima*, and their margins are much more deeply and conspicuously toothed. Any one planting a Forsythia for the sake of the beauty of the blossoms and a very free-flowering habit, would do well to select *F. Fortunei*, but if the graceful trailing habit is wanted it would not fill the requirements. It should be added, that this *F. Fortunei* is also sometimes sold as *F. viridissima*, in which case the purchaser is fortunate, for the last species, if true to name,

should never be selected in preference to the others unless space can be afforded for a collection of the various forms. The *F. Sieboldi* of some catalogues is merely another name for *F. suspensa*, and we have received at the Arboretum a *F. intermedia*, from German nurseries, which is hardly to be distinguished from the handsome erect form we know as *F. Fortunei*. It has been stated that some experimenters have grown both the *F. suspensa* and *F. viridissima* from the seeds of the former, but the two plants are so radically different that this hardly seems possible, and most probably there were mistakes somewhere. As the Forsythias are propagated by cuttings about as easily as Willows, there has been little inducement to raise plants from seed, but a series of seedlings from the different species or forms might be very interesting.

To the student of structural botany the efflorescence of Forsythia is interesting from the dimorphic character of the blossoms—that is, all the flowers of one plant will be found with long styles and short stamens, on another plant with short styles and long stamens—which facilitates their cross-fertilization by insects. It is of interest to note these differences, and in an examination of many plants in this vicinity we have found both the long and short styled forms among *F. suspensa* and also in the plant we know as *F. Fortunei*, but, so far, only the long-styled form in *F. viridissima*. The finding of both forms shows that the plants must have been originally derived from different seedlings, but our *F. viridissima* may all be the descendants of one original individual.

Arnold Arboretum.

J. G. Jack.

Lilies-of-the-valley.—These plants are forced into bloom and sold at so many seasons of the year that we are apt to lose sight of the fact that they are naturally flowers of May. At present nothing is prettier and more fragrant than their delicate bells nestling among the bold leaves. Naturally grown Lilies-of-the-valley have a beauty superior to those forced, though these flowers are acceptable at any time. There is always a demand for plants which can be grown under trees, and where the trees do not make an entirely dense shade, or where their gross surface-feeding roots are not fatal to any undergrowth, there are few things more satisfactory for such a position than Lilies-of-the-valley. An occasional thinning out and replanting of the crowns and a top-dressing of rich compost late in the season seem to meet their requirements in the garden. There is a noble variety of this plant of French origin known as Fortin. The specimens of this kind with which Messrs. P. Henderson & Co. favored me had grand foliage, but as they were spoiled in the forcing I am unable to say from experience whether the flowers are double the normal size as reputed. There is also a so-called rose-colored variety. This has small flowers, rather more constricted at the mouth than those of the type, and the color under glass entirely disappears. In the open the color is a rather feeble and unsatisfactory one.

Primula cortusoides.—This was lately mentioned as flowering in Massachusetts in April. It is seldom that flowers appear there before ours. My well-established plants are only now in full bloom; very satisfactory and graceful in flower in the border, but scarcely useful for cutting.

Iris cristata was noted last week as being in flower. This plant is too beautiful to dismiss without further mention, for, although a native plant and easily secured, it is one of our choicest border-plants. The foliage is very dwarf, only high enough to form a nest, filled and covered with large open lilac-colored flowers. It seems to me the most pleasing of all the dwarf true Irises.

Begonia Vernon (*B. semperflorens atropurpurea*).—As I may have unwittingly given a false impression of this plant last year, it may be well to note its behavior under exposure in the open. As stated before, the plants which had been kept under glass last year gave not the slightest sign of being other than a bright-flowered form of *B. semperflorens*. I transplanted them to a sunny border a few days since, and never beheld a more remarkable transformation in any plants. Within two days the deep green leaves began to take on bronzy and blood-stained tints of the most striking character, and the indications are that in this variety we have a new bedding-plant possessing many excellent points, easily and quickly propagated, bright, striking, showy and free-flowering, dark crimson usually. It should be a good wet-weather plant. Its ability to stand full exposure without scorching of the margin of leaves remains to be tested. It is certainly a variety worthy of trial.

The Forest.

The Profitableness of Forest-culture.

AT a meeting of the Genesee Valley Forestry Association, held in the Chamber of Commerce rooms at Rochester on the 10th of May, an address was delivered by Mr. B. E. Fernow, Chief of the Division of Forestry, Department of Agriculture. The extracts which follow are taken from a report of this address in the *Rochester Union and Advertiser*:

PROFIT IN FOREST-PLANTING.—So far as forest-planting for profit is concerned, I counsel you carefully to scan your conditions before you stake your fortune in that direction. With soil otherwise useless, with low cost of stocking the ground, with no extra expense in watching and managing, and with a market not overstocked when your crop is ready for sale, you may find your plantation one of the best and safest savings-banks where a few thousand dollars can be invested with fair returns in the end.

Aside from the financial result, you will receive, of course, many benefits arising from the existence of the timber-lot which it would be difficult to express in dollars and cents, and yet which are tangible and enhance the value of the surrounding farm-land by making the place more sightly, by furnishing shelter to cattle and crops; by preventing erosion of the soil, if on the hill-side; and, if large enough, by equalizing the flow of springs and brooks and insuring desirable subterranean drainage. Nor does the well-kept timber-plantation need to mature in order to attain its value. Soon the prospective value will be fairly recognized, just as the calf and the colt have in them the promise of becoming a cow and a horse and are valued accordingly.

LOOKING FORWARD.—Although there is still plenty of virgin timber in the country, the time when it will be comparatively exhausted is drawing near. We have in the United States about 500,000,000 acres in woodland. If all of this were in good condition, with full-grown timber on it—which is far from being true—there could not be found on it more than 1,500,000,000,000 cubic feet of wood, which is at the rate of 10,000 feet b. m. of saw-timber per acre in the average. Since we use annually from 20,000,000,000 to 25,000,000,000 cubic feet of wood, of which 30,000,000,000 to 40,000,000,000 feet, b. m., is saw-timber, it appears that even with these extravagant assumptions regarding supplies we would exhaust them in sixty or seventy years, assuming that new growth is consumed by increased requirements. That this increase takes place may be learned from my computation, according to which the values of forest-products and wood manufactures during the census years 1860, 1870, 1880 and 1890 amount to \$300,000,000, \$600,000,000, \$900,000,000, \$1,200,000,000 respectively, or an increase of thirty per cent. for every decade; and since it takes at least sixty to seventy years to grow saw-timber—what we now cut is usually twice as old or more—it would appear that whoever invests his money in forest-culture to-day must be amply repaid by the crop, albeit his children will reap the profits really. Certain it is that it always requires time, and quite a long time, before the results of such management become visible, and that is largely why people are afraid to stake their money in the business.

GOOD ROADS AND FORESTRY.—One of the first requisites to make any producing business profitable is to have a market for the product and to be able to readily bring your product to market. Good and permanent roads are necessary to insure continuous profits in forestry as well as in agriculture. The disgraceful condition of the roads through the United States almost everywhere is not only detrimental to good morals, but also to the pockets of the farmer and of the consumer of farm-products. For profitable forest-management good, permanent roads are indispensable. Their money value may be judged from the experience of the little dukedom of Brunswick, where, without any other changes, the building of a rational system of roads through its forest-domain increased the income from the forest-management by twenty per cent. That forest-management pays in Europe may not any further help our argument than to assure us that it pays under certain conditions. The conditions are, first, a dense population, which makes a market for every stick of wood down to the merest brush; a well-established forestry system which it has taken centuries to build up; wood-lawns in good or fair producing condition as a result of this long application of rational management; skillful foresters, who manage the Government forests and give advice and good example to private owners. Many a farmer there finds his wood-lot the best-paying and

never-failing crop, and there are communities, towns and cities where, instead of paying taxes, a dividend is paid to the citizen from the surplus resulting from the well-managed woodlands.

STATE FORESTS.—In the Government forests the annual net profits range from \$4.11 per acre of forest in the highly cultivated and densely populated kingdom of Saxony to \$1.19 in mountainous Bavaria, where the Government forests comprise 2,300,000 acres, on which the Government spends \$3,130,000, and gets in return \$5,880,000, netting \$2,730,000 every year, and giving besides employment to a large force of men. In Prussia the net annual profit for every acre of woodland was at the rate of \$1.31 on 6,000,000 acres woodland, the expenditure last year being nearly \$8,800,000 for the administration, and with prices in the woods of \$3.00 per cord of fire-wood in the average, and \$10.32 per 1,000 feet b. m. of saw-timber the returns were over \$17,600,000, netting \$8,835,119, and this is continuous, ever-increasing revenue.

Why should not the state of New York, now owning as state property twice the area which little Saxony owns in woodlands, and proposing to acquire additional lands so as to make the area between that of Bavaria and Prussia's Government forests; why should not New York make its Adirondack forests, if not as profitable, yet fairly so, as those states have made their woodlands pay? There are really only two difficulties in the way—these are politics and private greed!

Otherwise, with, say, 4,000,000 acres set aside as a reserve, if only half that territory is in fair producing capacity an annual cut of 250,000,000 feet would be a low estimate, and under skillful management the annual growth would soon represent double that amount, assuring a handsome revenue in years to come, besides securing a state park for health, pleasure, hunting, fishing, preservation of water-flow and lumber-supply, and all without expense. To bring this about it is necessary to secure as soon as possible the acreage before it becomes more expensive, to place it under competent administration, to open up and make accessible the wilderness by a rational system of well-built roads, and inviting, not keeping out the railroads, under such restrictions, to be sure, as will properly guard the forest against danger from fires; for accessibility is the keynote of practicable and profitable forest-management.

The lumberman can then be satisfied by selling the logs, the friend of nature will find plenty of opportunity to enjoy himself, the game will find the protecting thicket, which is now unknown, and the forest-cover, instead of decreasing, will be increased in density and quality under the skillful use of the axe by the forester. But the profitableness of forest-management in the Adirondack, like that of the wood-lot on the farm, cannot be stated altogether in dollars and cents, for its indirect value may far outstrip its direct revenue-producing value. As the properly placed wood-lot may protect the crops from injurious winds, give shelter to cattle, and keep the soil from erosion, and the water-flow of springs and brooks even, so the Adirondack forests, kept in proper condition, have an influence upon climate and water-flow for the whole state, and with it, upon its commercial condition and prosperity, which far outweighs the profits that may be derived from their timber, and this indirect profit it is that states and communities should have in view.

While, then, forest-culture may not be profitable in individual cases and for private purposes, it is always profitable for the community at large, for it insures favorable conditions in general and continuity of one of the most useful resources.

Correspondence.

The Winter-killing of Conifers.

To the Editor of GARDEN AND FOREST:

Sir,—A note in GARDEN AND FOREST concerning the injuries to Retinosporas and other conifers in the vicinity of New York, leads me to say that, although the winter here has been most severe, none of the conifers on my place have suffered in the least. Perhaps the injury to these trees in other places may be attributed to the drought in August and September of last year, which was very severe in some parts of the country, rather than to the cold winter. Thirty or forty years ago, whenever I lost an evergreen tree, I used to attribute it to the severe cold, and the same view was held by my friend, the late Winthrop Sargent, of Fishkill, with whom in those days I was in constant correspondence on horticultural subjects. But after many years of experience and close observation I have learned to give my trees much better cultivation, and have discovered that serious injury more often results from the

effects of dry weather in summer than it does from severe cold the following winter.

Of course, our winters here in New England are considerably colder than yours in New York, and if it was the cold alone which injured the trees in your vicinity we surely should have suffered more or less here. This is not the case, however. Of the numerous Spruces and Firs which I have been growing for many years there are twenty species at least which have not been injured by the winters for twenty years past. The Retinosporas do not seem to be quite so hardy as the Spruces, especially *R. pisifera* and some of its varieties. I have occasionally lost one of these, and the small branches die. I have plants of *R. squarrosa*, *R. filifera* and *R. obtusa* twenty feet high which have never been at all injured, and the same is true of *Thuopsis dolobrata* and *T. Standishii*, although they are not quite as large.

Wellesley, Mass.

H. H. Hunnewell.

[We attributed the injury to coniferous trees in this vicinity this year to very cold winds in March after a few unusually warm days. The injured trees, however, may have been weakened by the drought of last year. There can be no doubt as to the accuracy of Mr. Hunnewell's observation in regard to the effect of autumn droughts on coniferous trees. If the ground after a dry autumn does not get saturated with late rains before it freezes up for the winter, evergreen trees are certain to suffer more than others, for the leaves continue to transpire moisture to a certain extent all winter, while the water from rains and snows cannot penetrate to the roots through the hard frozen surface. If, therefore, the subsoil is dry—that is, if the roots cannot respond to the demands for moisture made by the leaves—the trees will suffer. We have a note from Mr. William Falconer stating that Mr. Charles A. Dana's collection of conifers at Dosoris, Long Island, suffered to a considerable extent, and the injury there was done in March, at the beginning of which month the evergreens were never in better form. Some of the Retinosporas, like the varieties of *R. pisifera*, especially *filifera*, suffered seriously; others, like *R. squarrosa* and *plumosa*, to a less degree, while the various forms of *R. obtusa* suffered least of all. It is worth noting, too, that at Dosoris, *Azalea amœna* came out unscathed, although it was in the teeth of the wind, and *Osmanthus ilicifolius* was also unharmed, while Broome, which had survived for years, was nearly killed, and Furze suffered still more.—Ed.]

Rose Sports.

To the Editor of GARDEN AND FOREST:

Sir,—An acquaintance of mine has a bush of the Baroness Rothschild Rose which has sported—that is, one of its branches has flowers which resemble the parent plant in form but are nearly pure white in color. Do sports of this kind always remain true when grafted, and will it be worth while to try to perpetuate this one?

Montclair, N. J.

C. R.

[It is always worth while to perpetuate a good Rose if it is any improvement on what we already have. The Baroness Rothschild is one of those varieties which have a tendency to sport, and we already have some good white-flowered plants from it as a parent. Mabel Morrison is one, and so is the *Merveille de Lyon*. There is no certainty, however, that any sport when grafted will remain true. Very often the first flowers from grafts will be identical with those of the original plant. These sports themselves are more liable to sport than other plants, and some of them lack fixity to such a degree that one can never be sure of them, although a portion of the grafts may continue to persist in the new form. Of course, stock and soil may have some influence upon the grafts, but, really, our knowledge of these matters is limited as yet, and we cannot account for many of the vagaries of sports.

We infer that the difference from the sport mentioned by our correspondent and its parent is simply one in the color of the flower. There are many other cases in which there is a distinct change in the habit of the plant as, for example, where some Rose, like *Victor Verdier* or *Niphetos*,

develops so-called climbing varieties. This means that from the original plant there will start some shoot which grows with remarkable vigor. The *Devoniensis*, for example, is not a strong grower, but its climbing varieties sometimes grow twenty feet in a season, although its flowers are true to the original type. Variations of this sort may be traced to some remote ancestor, but, so far as we know, this habit of growth is more liable to be fixed than simply variation of color.—Ed.]

Sweet Alyssum.

To the Editor of GARDEN AND FOREST:

Sir,—In summer-time no family owning the smallest lot of ground need be without a pretty centre-piece for the table if precaution has been taken to sow some seeds of Sweet Alyssum in April or May. This little plant thrives in any soil, and two packets of seeds sown in a bed or as a border will yield a plentiful supply of flowers the entire season through. They should be picked with long stems, and in plentiful quantity. The children of the family will do this work with pleasure, and they may also be taught to arrange the flowers afterward. A silver fern-dish is admirable for this purpose, but any low open bowl will answer, if it be but of glazed earthenware.

A piece of wire netting with meshes about half an inch square, a trifle larger than the top of the bowl, should be placed on the bowl when filled with water. Then set a blossom in each mesh, making sure that the stem reaches well into the water. The netting keeps the flowers in place; they stand more erect, and, in changing the water, it is only necessary to lift the netting, and replace it when the bowl is filled. By changing the water every morning a bowl of flowers will keep quite fresh for three days, as the stems do not crowd upon each other as they do in the old way.

Mignonette mingles well with Sweet Alyssum or Heliotrope or a few sprays of pink or red Geranium; but only flowers of one color should be used at a time, and these sparingly.

Brooklyn, N. Y.

Mary F. Harman.

The Flowers of Euphorbia.

To the Editor of GARDEN AND FOREST:

Sir,—Your correspondent O. O. makes a very natural mistake when he says, on page 224 of your issue for May 11th, that it is the flowers that are ornamental in the case of the *Euphorbia jacquiniæflora*. Referring to Gray's *Field, Forest and Garden Botany*, we read: "*E. fulgens*, or *jacquiniæflora*, . . . what appears like a 5-cleft corolla are the bright red lobes of the involucre."

Milton, Mass.

Nathaniel T. Kidder.

Notes.

The Diet of the Tyrol recently decreed that a heavy fine shall be imposed upon any person offering for sale a sample of Edelweiss that has been pulled up by the roots.

We have received a photograph from Mr. W. B. Hartland, of Cork, Ireland, of a mass of Horsfield Daffodils planted thickly over a bed of about a hundred square feet in extent. Judging from the picture, these plants have wonderful vigor and attain remarkably good form in the "old country."

The white flowers of the Black Haw are beautifying many of the road-side thickets within a few miles of this city, and there is no more attractive small tree or large shrub than this native *Viburnum prunifolium* as it appears in our woods and parks. Besides the beautiful flowers, the bright red bark of the young twigs and the reddish tint of the young leaves add to the beauty of the plant, and the foliage is no less striking in autumn, when it turns from its bright green to rich orange and purple.

The earliest Pæonies to bloom, and they are now at their best, are the varieties of *P. tenuifolia*. These are not new plants by any means, but since they are so easily cultivated, so perfectly hardy and so beautiful, it is remarkable that they are not more common. The single form is especially beautiful with its dark crimson flowers, which are borne on stems some fifteen or eighteen inches high surrounded by finely cut foliage. The double-flowered forms are also very beautiful, and the foliage is rather more delicate.

A preliminary announcement, with schedule of prizes for the Chrysanthemum Show at Madison Square Garden next fall, has been issued. The exhibition will be under the auspices

of the New York Florists' Club, and will be held from November 1st to the 6th inclusive. Six thousand five hundred dollars in premiums are already offered, and it is probable that a supplementary prize-list will be issued later. We are glad to observe that preparations are being made for a spring show next year, and that exhibitions both in the spring and in the autumn may be expected every year hereafter.

Flowering specimens of Bechtel's double-flowered American Crab have been sent to us by E. A. Bechtel's Sons, of the Staunton Nursery, Staunton, Illinois. It is a double-flowered variety of the western form of *Pyrus coronaria*, which botanists have called variety *icensis*, and is said to have originated in the neighborhood of Staunton. The flowers are pink, very double, and, like those of all the native Crabs of eastern America, delightfully fragrant, in this respect being far superior to any of the double-flowered Crab-apples in cultivation. The fact that the flowers are not produced until the leaves are almost fully grown, and much later than those of any other Apple-tree, adds decidedly to the value of this novelty, which, judging by the specimens before us, is one of the most beautiful hardy plants of recent introduction.

A writer in the *Boston Evening Transcript* declares that the plantations made by the Boston and Albany Railway Company around its suburban stations have had a decided influence in improving the horticultural taste of the people living along its lines, and that good plants, like *Forsythia Fortunei* and other hardy shrubs, have been made common and popular in this way. The scheme under which these plantations are made has already been described in these columns. The station-grounds are decorated with trees and the best hardy shrubs, preference being usually given to native species, as being more hardy and generally more satisfactory than exotic plants; no bedding or tender plants whatever are used, the effect being obtained from well-kept lawns, skillfully arranged shrubberies, in which it has been aimed to secure a succession of flowers, handsome fruit and brilliantly colored autumn leaves.

A correspondent of *Gartenflora*, writing from Orizaba, in Mexico, says that one of the most beautiful flowering plants to be seen there is *Datura arborescens*. "It is a native of Peru, but flourishes finely here. Where sufficient room is given, it develops as a broad shrub some fifteen feet in height, and at almost every season of the year is covered with a profusion of large, dazzling white flowers. The burden of these flowers weighs down the branches, but the beauty of the plant is merely increased by this fact. The double sort grows even more luxuriantly. Native Mexicans usually train these plants as standards with a flat, wheel-shaped head, from the under side of which depend the many blossoms. But, to me, their natural manner of growth is even more attractive." This tree-like shrub is sometimes cultivated in our conservatories, but to those who have not seen it there the description we quote will scarcely suggest its intimate relationship to *D. Stramonium*, our common Thorn-apple or "Jimson-weed."

We received last week a large package of cut Orchid-flowers, mainly *Cypripediums*, from the collection of Mr. T. F. MacFadden, of Cincinnati, Ohio. Among them were several spikes of *C. Rothschildianum*, each with four well-expanded flowers, and one splendid form with three flowers of great size and extraordinarily rich coloring. Unlike many other *Cypripediums*, the blossoms of this one remain on the spike until all the buds are opened, which makes it very desirable. There was also a six-flowered spike of *C. leucorrhodum*, with a superb variety of *C. selligerum majus* carrying three flowers. Among other handsome flowers were some of *C. Schroderæ splendens*, fine examples of *C. grande* and *C. alborpurpureum*, several distinct and unusually richly colored flowers of *C. Curtisii*, with good examples of *C. almun*, *C. macropterum*, *C. niveum*, *C. bellatulum* and many others. The flowers, as a class, showed unusually good care and cultivation, and reflected great credit on Mr. John Rose, the gardener, who has this fine collection in charge.

We received last week from E. O. Orpet, South Lancaster, Massachusetts, a collection of *Narcissus*-flowers in some forty varieties, representing the choicest kinds in all sections. The flowers were well grown, and formed beautiful, graceful masses. All the leading kinds were represented, and there were many interesting ones seldom seen and not often found here. In the Ajax section, P. R. Barr was noted as a very bold, full, yellow flower. Of the Discolors, James Walker and Michael Foster were beautiful and distinct. The collection was rich in the *Incomparabilis* section. Some distinct kinds were Barr's *Conspicuus*, *Orphée* and Maurice Vilmorin, all with

deeply stained orange cups. Hume's Giant was an extra distinct flower with broad-spreading cup and a good clear yellow. The forms of Burbridge's hybrids, the connecting link between *N. poeticus* and *N. incomparabilis*, were very charming, and were represented by a selection of the best kinds—Crown Princess, pure white perianth, canary cup, edged scarlet, a rare and distinct kind; Constance Falstaff; John Bain, a charming flower with citron cup and white perianth, and the rare Princess Louise, with widely expanded deep orange-scarlet cup and large white perianth.

Among the many schools for summer study which are promised for the present year will be a course of instruction in horticulture at the Bussey Institute, beginning on July 6th and ending on August 3d. A synopsis of the lectures which are to be delivered by Mr. B. M. Watson, Jr., shows that the instruction will cover a wide range of subjects which will be of scientific and practical value to students of horticulture. These subjects will include soils, propagation of plants by various methods, grafting, construction of glass-houses, insects and fungi, hybridizing, pruning, and others of equal importance. Supplementary lectures will be given from time to time, when the exercises will be held in the open air, and illustrated by visits to the more important classes of plants in ordinary cultivation, such as conifers, flowering shrubs, herbaceous plants, garden-annuals, house-plants, grasses, *Rhododendrons*, *Roses*, *Chrysanthemums* and *Lilies*. In addition to the instruction in the theory and practice of gardening and the field-talks already spoken of, there will be opportunity for practical work in both greenhouse and garden. About eight hours a day will be devoted to work of different kinds, and the course will be open to women as well as men. The collection of trees and shrubs at the Arnold Arboretum will give ample opportunities for illustrating this course, which is one of the new undertakings to which all those interested in horticulture will wish the highest success.

In addressing the Association of American Cemetery Superintendents at Chicago last autumn, Mr. Eurich, of Toledo, Ohio, said, with regard to plants that can be used to cover the ground beneath trees where grass will not grow, that he had experimented successfully with two "sod-forming" plants, *Herniaria glabra* and *Veronica repens*. The first-named, he explained, "is a moss-like, creeping plant which covers the ground in a very short time, and surpasses a grass-sward in beauty. A strip of ground was planted in April with one hundred such plants set apart, and in less than two months the entire surface was covered closely. The plants were thinned out so that we obtained more than twice the original number, and an adjoining new piece was planted with the same result. This procedure was repeated in August, and before winter set in we had a beautiful greensward of *Herniaria* growing. A very cold winter followed, and the plants were tinged slightly brown, but by April were again charmingly green. *H. glabra* will thrive in any soil in the open sun or in the shade." *Veronica repens*, the speaker said, "has somewhat larger leaves of shining green and generally the same characteristics as *Herniaria glabra*. A grave-mound planted with it in August was completely covered by fall, and with a slight protection during the winter was brighter and fresher than the mounds covered with Myrtle (*Vinca*) and Ivy. The special feature of this plant is that in May it is completely covered with very light blue flowers as low as the plant itself."

Edward von Regel, the venerable Director of the Imperial Botanic Garden at St. Petersburg, died on the 27th of April, in his seventy-seventh year, he having been born at Gotha on August 13th, 1815. Regel was first established at Zurich, but many years ago was called to the directorship of the St. Petersburg garden, which he has labored assiduously to bring to its present state of efficiency. He was the author of a large number of botanical works devoted mostly to the description of plants collected by Russian travelers in central Asia. He was the founder and for many years the editor of the *Gartenflora*, and in the Acts of the St. Petersburg garden are many papers upon garden-plants from his pen. To Regel, more than to any one else, is due the success of the International Horticultural Exhibition held at St. Petersburg in 1869; and he has enriched the gardens of America and Europe by his liberal distributions of the seeds and plants gathered by his correspondents in all parts of the vast Muscovite empire. No one has surpassed him in this or in his desire to serve his associates, and to the intelligent zeal and broad-minded liberality of this active and industrious man is due the introduction of many of the best plants which have been brought into gardens during the last twenty-five years.

Good Taste in Our Cemeteries.

WE spoke last week of the views of certain prominent American cemetery superintendents, as expressed at the last meeting of their association, with regard to the aspect which our rural cemeteries should wear. We quoted their own words to show that their ideal of a cemetery is a simple, peaceful place in which a natural, rather than an artificial, type of beauty has been secured; a place not crowded with costly and showy monuments or rendered garish by gaudy flower-beds; a place neatly kept, although not trimmed and polished into the semblance of a public park or a private garden. And we said that, according to their witness, this ideal would be more often attained were it not for opposition to the plans of superintendents on the part of their employers.

This opposition was not dwelt upon in any carping or militant spirit by any of the speakers; but all the addresses clearly suggested it as a thing which need not be dwelt upon because already so generally recognized as the chief bar to the improvement of the average American cemetery. Here and there we find in the report of the speeches a more definite statement, as, for instance, with regard to the "prevailing anxiety" of lot-owners to "compete with each other" in the erection of conspicuous, ugly monuments; and, again, with regard to the popular demand that flowers be planted "profusely," and the difficulty in meeting specialized desires of this sort—of having any assurance that the flowers will be planted artistically rather than ridiculously.

"When we have said all we can," remarked one superintendent, "there still remains the fact that the public are the patrons of every cemetery association. The public, consisting of many men of many minds, to their wishes and desires we must all, to a great extent, conform. We may denounce pathways, stone-work, flowers, shrubs and borders, and lay down methods of burial and selling of

lots, and advocate perpetual care, but we cannot adopt any hard and fast line of refusal or enforce arbitrary rules; even by-laws have occasionally to be overlooked to satisfy the public." And another speaker drew a picture of the appearance of a cemetery to which he was appointed, which has, we think, a certain typical significance. "Every lot-holder," he said, "had been permitted to plant and decorate as he desired. To add to this, seedling and volunteer growth abounded, and the management was permeated with the sentiment of 'Woodman, spare that tree.' Receptacles for flowers of every imaginable construction—iron, wood, tin, glass, china—the greater number of them unfit for any other purpose, were considered just the thing for decorating the cemetery-lot. No uniformity of grade existed, some lots being high, some low; there were big mounds and little mounds, and many of them transformed, becoming depressions in the ground, and many of them selfishly enclosed with several hundred iron railings in various conditions of neglect. . . . In one day I swept off the lots six great cart-loads of conch-shells and their contents. In the ideal cemetery," continued this speaker, "there are no paths nor space laid out for walks. The boundaries of the lots are out of sight—no posts, no foot-stones, no head-stones, no mounds to designate a grave, but a succession of beautiful lawns broken only by a single monument upon a lot. The irregularly shaped lots allow space for the planting of trees in groups and single specimens and the arranging of flowering shrubs for foliage effects."

The contrast between these two pictures is instructive, and shows pretty fairly what a rural cemetery often is when controlled by the taste of the community and what it may be if really controlled by such superintendents as are now available. To some readers the ideal picture may seem exaggerated. No person of taste will insist that the boundaries of lots should be conspicuously marked, that graves or the borders of lots should be turned into crazy-quilts of flowers, or that monuments should be so numerous and striking that the cemetery will look more like a marble yard than a place of eternal repose. But to limit owners to a single monument in each lot may seem to be an exaggeration of the desire for a "natural" effect. In truth, it is not desirable that the true character of a cemetery should be so carefully concealed that it might be taken for a park or an uncultivated piece of nature. It ought, of course, to look like a burial ground, although like a simple, quiet, peaceful, unostentatious burial ground. And, if monuments are kept of small size and are designed in simple yet artistic ways, there is no reason why lot-owners should each be limited to one. There is, however, a good reason for doing away with those grave-mounds to which traditional sentiment so strongly clings. In the first place, they are constant temptations to the introduction of floral ornamentation of too striking and gaudy and, at the same time, too ephemeral a sort. And, in the second place, if they are covered with turf, it is hard to keep them and their immediate surroundings neat. Labor is so costly in this country that the lawn-mower must be the chief if not the only aid toward neatness in the lawns. And mounds over which the lawn-mower cannot pass are almost sure to be detrimental to the general effect of a cemetery. So it also is, of course, with boundary stones around the lots; even if they are kept so low that they do not unpleasantly affect the eye, it is impossible properly to cut the grass around them.

In general, the ideas of this Association of Superintendents, as expressed by the chief speakers at their last meeting, seem worthy of cordial endorsement; and we feel with them, not only upon their evidence but also upon that of our own observation, that the chief thing now to be accomplished is the education of the public taste in such matters. The taste of many superintendents is evidently far in advance of that of their patrons, and it is probable that even those whose taste is still on a level with this would quickly meet the wishes of their patrons should these take a better direction. No person in charge of a

cemetery, even if his own taste is still crude, is likely to cling, against the desires of his patrons, to traditional crudities, mistakes and abuses which largely increase the difficulties of his task and force him to spend a great deal of money to preserve his domain even in a tolerably neat condition.

There is only one serious fault which we find in any of the addresses from which we have quoted. This is a fault in expression, in terminology, rather than in idea. Nevertheless, so strong is the influence of terms upon thought, that it may give rise to mistaken ideas in other minds. The excellent address of Mr. Scott, of Chicago, in which he pleaded the cause of natural beauty in the cemetery, was unfortunately entitled "Nature versus Art," and was in answer to the question, "Should not Cemeteries present more of Nature and less of Art?" Had "artificiality" been substituted for "art" in these titles the subject would have been more justly presented. What the speaker was really pleading for was not nature, which means beauty that man's hand has played no part in creating, but a kind of art in which the leadings and teachings of nature's types of beauty are discreetly followed. A cemetery planned and maintained as Mr. Scott would have it is a true work of art. One that is badly designed, untidily kept, and overcrowded with inappropriate monuments and flower-beds, is not a work of art. It is an ugly, artificial, inartistic thing. In condemning it and its customary contents, Mr. Scott need not have protested, "Far be it from me to condemn art" in its proper place. For he was really pleading the cause of art while nominally pleading the cause of nature. The fact that practical considerations with regard to ease in labor and cheapness of methods largely entered into his considerations does not invalidate his position as an advocate of true art. There are many artistic enterprises in which practical considerations are very important; and, as in the case of the architect, for example, he is the best artist who can to the best advantage deal with questions of every-day convenience, cost of construction, ease of maintenance and the like while working out with the highest taste and skill the artistic side of his problem.

A WRITER in *Gartensflora* recently complained with bitterness of the aspect of florists' shops in Berlin. Here in America there is sometimes occasion for just complaint that florists fail to secure the highest effect which an artistic arrangement of their stock might produce. But in Berlin it seems that errors of commission are much more distressing than the occasional errors of omission here. For instance, the present fashion, says the writer in *Gartensflora*, is to encircle all blossoming plants which are offered for sale with cones of the most gaudily colored "calico-paper," so that the plants themselves are almost concealed from sight, and, of course, when they are visible, show to the worst advantage. To this custom the writer attributes a great recent decrease in the sale of potted-plants, although he explains it by saying that it springs from the natural desire of purchasers not to soil their hands and clothes by contact with the pots. This explanation we may in turn explain by saying that our practice of having all goods delivered at our homes by the shop-keeper does not largely prevail in Germany, where even the family marketing is usually carried home by the house-wife or her servants. The writer then says that, in another direction, good taste is increasing, for the once beloved "mosaic bouquet" has given place to what he calls the "true German bunch of flowers." To an outsider it may seem that this new taste for naturally cut flowers may have been imported into Germany from Paris or America. But, at all events, the Berliners might learn from Paris to use sheets of pure white paper for enveloping flowering plants. Were the innumerable white cones removed from the plants, which once a week crowd the great steps surrounding the church of the Madeleine, the gayety and beauty of one of the most charming scenes that Paris offers would be grievously impaired.

The White Oak at Shandy Hall, Maryland.

WE have already published several pictures of the White Oak, but in order to give a complete idea of any species it is necessary to study many specimens, both in full foliage and in the winter, when the absence of leaves shows more clearly the texture of the bark and the ramification of the branches. The White Oak, when it has room for full development, is one of the noblest of our deciduous trees, and the specimen which is illustrated on page 259 is one of the comparatively few which have escaped the general destruction of the primeval forests in the earlier-settled portions of the country. It is situated at Shandy Hall, in Maryland, about eight miles below Havre de Grace, on the mainland opposite Spesutia Island. The tract of land which has borne the name of Shandy Hall for several generations was taken up on the first settlement of Harford County, and the original deeds, in the possession of Mrs. Anna E. Barnard, bear the royal seals and are dated 1640. The property has always remained in the possession of the Hall family, which is an unusual thing in our country, where local attachment does not seem to be developed as strongly as it is in the older countries of the world. That this tree is very old is plain not only from its size, but from the fact that in a deed dated 1676 it is called the Big Spreading Oak, and a boundary stone, which is alluded to in the deed as standing under the tree, remains there still. Near the ground the trunk of this tree measures thirty-six feet in circumference, and just below the first limb it is twenty-two feet in circumference. The spread of the branches is unusually large, and covers a circle of 122½ feet in diameter. It is still in good health, and seems sufficiently vigorous to last another century at least.

Mid-May in West Virginia.

THAT enchanting fortnight, when the fruit-trees seem to have foliage of flowers, is over now, and all the loveliness of Apple-bloom is past. Here and there a massive, well-rounded Horse-chestnut shows its great white clusters, and a deep-red variety is very handsome. Horse-chestnuts seldom combine effectively with other trees; they are best in isolated positions or in clumps of three or four. The shade they throw is so dense that grass does not flourish beneath them; it is well to take this fact into consideration when designing the home-grounds, and not plant them too near the dwelling.

The latest of the Amelanchiers is the variety *Floribunda*. This blooms about three weeks after the earlier *Shad-bushes*. The petals of the small-flowered clusters are rounded, not elongated like the other varieties, and the pink-tipped stamens are very pretty; but the plant lacks the fragile elegance of *A. Canadensis*. It has somewhat the appearance of a blossoming Pear, except that the flowers are smaller, and it makes a pretty little tree from ten to twenty feet in height. The bloom of this variety is now fading.

The flowers of the common Snowballs and the Japanese *Viburnum plicatum* are gradually whitening under the warm sunshine. Weigelas are opening their buds, and the day of the flowering Dogwoods is nearly over.

Coronilla Emerus, *Cytisus purpureus* and *Caragana Cham-lagu* now represent the Pulse family in the shrubberies. The *Cytisus* is quite covered with its papilionaceous blossoms of pink and cream, and is an exceedingly pretty, small shrub; useful for planting close to a piazza or on the outer margin of shrubberies. Like *Daphne Cneorum*, one wants it close at hand and apart from free-growing shrubs, which would rob it of light and nourishment. It remains a long time in flower.

Some upright or bush Honeysuckles are now flowering; but perhaps the queen of the shrubbery at present is Paul's beautiful double variety of the Hawthorn, *Crataegus Oxyacantha*. Its flowers look like small double roses, of a rich carmine color, and the tree seems perfectly healthy, free from insects, and a more rapid grower than most Thorns.

Last year, and the year before that, we found the first rose on the third of May; but the cold spring of this year has retarded all vegetable growth, and it was not until May 18th that the first Cinnamon and Scotch Roses ventured to disclose their beauty. A few more days of the warm sunshine we are now having will transform the home-grounds into a Rose-garden; an Eden into which, alas! the enemy will find

entrance in the shape of myriads of bugs and slugs, the inevitable accompaniment of the blooming Rose.

Elaeagnus longipes is now flowering profusely. The tubular, four (sometimes five) parted blossoms closely scattered over the twigs are cream-colored when they first appear, yellowing with age. They have a strong, not altogether delightful, odor, by which the bees find them out and hasten to the revel it proclaims. The Barberries also hold out many seductions to men and bees, and charm more senses than one. Nothing can be finer than a tall, graceful purple Barberry in full bloom, standing in the sun. Its yellow petals have plum-colored markings on the under sides, to match the rich coloring of the leaves and young twigs. These Barberries need bright sunlight to develop their beauty. They are dull of hue when planted in the shade; the outer leaves are always richer in wine shades, the inner foliage usually reverting to green.

Several fine *Spiræas* are now at their best. The long drooping wreaths and garlands of *S. Van Houttei* have a snowy whiteness and grace which makes the shrub conspicuous at a distance, and it rather gains than loses by close inspection.

S. Cantoniensis (known in many nurseries as *S. Reevesiana*) is coming into flower. I learn that it cannot always be trusted to live through New England winters, but in this latitude it is one of the very best spring-flowering shrubs.

Nevuisia Alabamensis is still beautiful with its delicate flowers of white and green. These last a long time, and know how to grow old gracefully; the absence of petals preventing the unsightly appearance many shrubs present in the fading stages.

Japan Maples are in full foliage, and their colors are at their brightest. The hot suns of July and August will dull them, but they brighten again under the skies of autumn.

The fresh green of the new growth on many conifers enlivens the sylvan picture; and all of the deciduous trees, with one exception, are now in leaf. This exception is an *Acacia* or *Albezzia*, of whose proper name I am doubtful; a beautiful, small tree, with foliage resembling a Sensitive Plant, which is described in some nurserymen's catalogues as *Acacia Memu* or Japanese *Acacia*, and is said to have pink flowers. Ours has never bloomed, and is always the very last of our plants to unfold its beautiful leaves.

Honey Locusts, Paulownias and Paper Mulberries are among the latest of trees to leaf, but these are all well under way and have made great progress in the last two days.

The Red-branched Dogwood is no longer worthy of the name, its brilliant coloring having passed away, or being confined to the twigs that bear the flower-clusters. It is at all seasons a handsome shrub.

Rhododendrons are beginning to bloom, and many Azaleas are now in their prime. The hardy Azalea is a plant that requires very skillful management. The colors are so apt to quarrel, and to require separation after the groups are formed. Such dissension in one family is unfortunate. I am inclined to prefer the wild Azaleas to any of the imported varieties; the colors are not so glaring. Of course, the bright magenta and the flame-colored types should never be planted in juxtaposition, yet how often this is done. If perfect accord is wanted in the garden, they should not be in hailing distance of each other. Groups of Azaleas of harmonizing hues are much more effective than single specimens, and it is well to plant them where they will have some dark evergreens for a background.

Rose Brake, West Va.

Danske Dandridge.

A Sequence of Flowering Cherries.

WRITERS on Japan constantly tell of the love the Japanese have for flowers, of the various favorite varieties, and of the national fêtes in honor of them. We are told that one of the plants so highly honored is the Cherry, and that every spring-time there are Cherry-blossom festivals which have something of a national character. It frequently happens that the illustrations of Japanese subjects furnished by artists, in which Cherry-blossoms are supposed to be represented, give us what appear to be Peach or Apricot flowers, and it is quite likely that they should have been called so, from a correct and botanical point of view.

That there are most beautiful species or varieties of flowering Cherries in Japanese gardens we know by a number of plants which have been introduced into cultivation in Europe and America. One of the earliest-flowering of these, as it is of all the species with which we are acquainted, is what is considered to be *Prunus pendula*, or a form of it, which has been derived from nurseries under the name of *P. (or Cerasus) Sieboldii pendula flore rosea* and *Cerasus Japonica rosea pendula*. This season the first blossoms of a particular plant

opened about April 25th. It was in full bloom about May 2d, and continued to be a conspicuous and very beautiful object for fully ten days longer.

The flowers, which are produced in fascicles of three or four from a bud, and on long slender stalks, are pale rose-colored, and appear before there is any indication of leaves. The calyx and calyx-lobes and portions of the flower-stalks are of a dark red color. The flowers are produced in great profusion, and apparently there is no appreciable variation in their abundance every year, which adds much to the value of the plant for ornamental purposes. The fruit is very small, being hardly larger than a pea, of a dark red color, sour and with little pulp. It has not been produced in sufficient abundance here to be ornamental on the plant in the fruiting season, so that, except for the blossoms and its pendulous habit, it has no other special claim for ornament or utility. Its specific name of *pendula* is well applied, for, although the main branches are horizontal or diverge from the trunk at an upward angle, they ultimately assume a widely arching form, the extremities and all the lateral branches being pendent or pendulous. The largest specimens here are now from fifteen to eighteen feet high, and the indications are that they will not grow much higher.

A plant of similar habit, but with variations in the leaves and color of the flowers and some minor details, is sold from the nurseries under the long name of *P. (or Cerasus) Sieboldii pendula flore carneo*, although the *pendula* is sometimes left out. It is also distributed as *Cerasus Japonica pendula rosea*, and under other names. From a horticultural standpoint its peculiarity and value consist in its flowers being of a deeper red color than those of *P. pendula*. As noticed here it blossoms a day or two later, and its branches have a more angular and less graceful habit. Its fruit is similar to *P. pendula*. Whether they are distinct varieties, from a botanical standpoint, should be proved by raising each from seed. The darker-flowered form is generally considered not as beautiful as the other variety, whose blossoms are so peculiarly and delicately colored as at once to suggest something Japanese, and which is not surpassed in beauty by any other tree of its class of which we know.

Both of these grow exceedingly well when grafted on the common Cherry. They should be grafted so that the point of insertion is at or below the surface of the ground, because the Cherry-stock apparently grows much faster than the cion, and unnatural disproportions in the trunk are always a serious disfigurement, and to be avoided. In specimens in the Arboretum, grafted at the ground on common Cherry, the stock has developed into a large woody mass or base, upon which the trees seem to rest.

There are flowering Cherries from Japan and China which belong to a different type, and which are passing under a variety of names. These are small trees, with closer affinities with, and aspect more like, the common Cherries of our gardens, but differing from them in having conspicuously branched or forked flower-stalks, several flowers being attached by their pedicels to a single stalk common to them all, instead of every flower appearing to have a separate stalk from near the base or bud. There are two distinct forms, and although both have sometimes been placed under the Asiatic species known as *Pseudo-Cerasus*, they are probably representatives of very distinct species. Both of the kinds most common in cultivation have double or semi-double flowers. The earliest to blossom, the first flowers appearing about the first week of May here, blooms before the leaves have fairly expanded, and has petals of a rosy white or bright rose-color. Its leaves are of a dark green color, and are quite pubescent beneath. The flowers persist for two weeks or more in good showy condition. Among other names this plant is to be had from nurseries as *P. (or Cerasus) Pseudo-Cerasus rosea plena* and as *Cerasus Watereri*.

The other type comes into bloom a full week later. Its blossoms appear with the foliage, and are of a clear china white, the outer petals sometimes flushed with a rosy color, the whole flower when old often having a roseate tinge. It is characterized by lighter green leaves, with smooth leaf-stalks, smooth and shiny on the upper surfaces and glabrous and pale beneath. The calyx is only five-parted, while in the pubescent and dark flowered form there are usually seven or eight divisions. There are numerous other points of difference, and when the plants are seen growing side by side there appears good reason to keep them botanically distinct. The white-flowered form is known by nurserymen as the Double Chinese Cherry, *P. (or Cerasus) serrulata* and *P. Sieboldii alba plena*. It is apparently not so floriferous as the other. Neither of these Cherry-trees, as we have them, assumes a regular form

but are inclined to be rather one-sided in habit, and from data at hand can hardly be expected to attain a greater height than from ten to fifteen feet. They can be more readily grown from cuttings than many others of the same family, but such plants are found to grow so slowly that it is better to propagate by grafting in the usual way.

While none of the species already mentioned attain large size, the double-flowered form of the European Bird Cherry (*P. Avium*) becomes a stately tree, and some old specimens in this vicinity, now thirty or forty feet in height, have been most beautiful objects with their heavy loads of snowy white double flowers on long stalks in clusters of several from a bud. The period of best bloom is usually about the middle of May here, the flowers being simultaneous with those of the white-flowering Japanese Cherry just mentioned. No double-flowering Cherry surpasses it in effective beauty of its bloom, and since it becomes a large tree it requires room for growth and full development. This tree is to be obtained as *P.* (or *Cerasus*) *Avium alba plena* or *P. Avium multiplex*. Instead of *P. Avium* we occasionally find it classed as *P. Cerasus*, which is a separate and distinct species, and from which a double form has also been derived. This is sold by nurserymen as *P. Cerasus ranunculiflora*, or *flore pleno*, or *Cerasus Caproniana ranunculiflora* or *multiplex*. In the confusion of names it is also occasionally found under *P. Avium*, from which it may be distinguished by its perfectly glabrous, shining, almost sticky leaves, which appear much later than in the other variety. Its blossoms, also, do not begin to develop until about two weeks after the first flowers of the double-flowering *P. Avium* are seen, and it is the latest of the strikingly ornamental Cherries to blossom. The flowers are quite as double as those of the other species, but are less graceful and have a greenish centre, and the tree does not attain anything like such a large size.

Arnold Arboretum.

J. G. Jack.

New or Little-known Plants.

Asarum Crux-Andræ.

ASARUM is a small east temperate North American and Antillean genus of a few subfruticose plants with black dotted leaves and solitary yellow flowers, of the Hypericums family, principally distinguished from the true Hypericums by their four, instead of five, unequal sepals, their numerous distinct, not clustered, stamens, and ovoid capsules. The species are little known in gardens, although *Asarum Crux-Andræ*, of which a figure appears on page 257 of this issue, in spite of the fact that it is rather delicate in cultivation, is a good subject for the rock-garden or the margins of small shrubberies, as the habit of this little plant, which, under favorable conditions, spreads into broad mats of bright foliage studded during several weeks in summer with clear yellow flowers, is well suited for such purposes. The much-branched stems rarely rise more than four or five inches above the ground, and are thickly clothed with small narrow obovate-oblong leaves, furnished with two glands at their bases. The shape of the flowers is interesting, and to their peculiar form is due the name by which this plant is known, St. Andrew's Cross. Of the four sepals the two outer are broad, flat and ovate, and the two inner are minute and almost hidden by the petals, which are linear-oblong, acute, arranged in the form of an X, or St. Andrew's Cross.

Asarum Crux-Andræ is not rare on the island of Nantucket; it is rather a common plant in the New Jersey Pine-barrens, and ranges to Virginia, southern Illinois, eastern Nebraska and eastern Texas. It has been an inhabitant of the Arnold Arboretum for several years, but it is not very hardy here, and demands dry, rather sandy, well-drained soil and careful protection in winter.

Of the other species of the genus, none of which appear to have been introduced into gardens, *A. pumilum* inhabits the sandy Pine-barrens of Georgia and Florida; *A. hypericoides*, a taller plant with erect stems sometimes two feet in height, ranges from our south Atlantic and Gulf states to the West Indies; *A. stans*, with large broad petals and showy flowers, is distributed from New Jersey along the coast of Texas, and is a handsome plant, which may be expected to make a useful addition to the

list of small garden-shrubs; and *A. amplexicaule*, an erect-stemmed plant with large clasping leaves and bright yellow flowers an inch in diameter, is a native of the south Atlantic states and of Cuba.

C. S. S.

New Orchids.

DENDROBIUM × **ROLFEÆ**, Sander. — A charming hybrid, raised in the establishment of Messrs. F. Sander & Co., of St. Albans, from *D. primulinum* crossed with the pollen of *D. nobile*. It has large delicate-colored flowers, in which the influence of the pollen parent decidedly preponderates. — *Gardeners' Chronicle*, April 23d, p. 522.

VANDA ARBUTHNOTIANA, Kränzlin. — A species allied to *V. Roxburghii*, with golden-yellow flowers transversely striped with purple. It is a native of the Malabar coast, and was introduced by Messrs. F. Sander & Co., of St. Albans. — *Gardeners' Chronicle*, April 23d, p. 522.

CATTLEYA ALEXANDRÆ, L. Lind. & Rolfe. — A very remarkable species, with long peduncles fifteen to eighteen inches long, and bearing six to ten flowers at the apex. These have the general shape of those of *C. Leopoldii*, the sepals and petals being of a coppery brown tint, shaded with violet on the undulate margins, and the lip violet-rose. — *Gardeners' Chronicle*, April 23d, p. 522.

CYPRIPEDIUM EXUL, O'Brien. — A Siamese species, introduced in 1891 by two or three different firms, which has recently flowered for the first time in Europe. It is the *C. insigne*, var. *exul*, of Ridley, but is specifically distinct, and in several respects is more nearly allied to *C. Druryi*. It received an award of merit from the Royal Horticultural Society on April 19th last, when exhibited by R. I. Measures, Esq., of Camberwell. — *Gardeners' Chronicle*, April 23d, pp. 522, 523, fig. 77; also p. 535.

CATTLEYA × **BURBERRYANA**, Sander. — A new hybrid raised in the establishment of Messrs. F. Sander & Co., of St. Albans, who received a first-class certificate for it from the Royal Horticultural Society on April 19th last. Its parentage is stated to be "*C. imbricata* × ♀ [*?* × *intricata*] *superba* ♂." The flowers are said to resemble the latter in shape, the sepals and petals white tinged with pink, and the front lobe of the lip rich crimson. — *Gardeners' Chronicle*, April 23d, p. 535.

CATTLEYA × **PHILO**, Veitch. — A hybrid raised in the establishment of Messrs. James Veitch & Sons, of Chelsea, from *C. mossiæ* crossed with the pollen of the rare *C. iricolor*. The sepals and petals are blush-white, with a faint yellow tinge, the front of the lip crimson with a blush-white margin, the middle of the lip yellow, and the base crimson with whitish veining. It received an award of merit from the Royal Horticultural Society on April 19th last. — *Gardeners' Chronicle*, April 23d, p. 535.

CYPRIPEDIUM × **HUYBRECHTSIANUM**, Vervaet. — A name applied to a hybrid raised between *C. hirsutissimum* and *C. Spicerianum*, which particular cross has already received no less than three distinctive names. Chronologically arranged these are *C. × Medeia*, *C. × Ceres* and *C. × Vanmolianum*. — *Gardeners' Chronicle*, April 30th, p. 554.

Kew.

R. A. Rolfe.

Plant Notes.

Some Recent Portraits.

IN the May issue of *The Botanical Magazine* are figured *Lilium Lowii* (t. 7232), another of the fine Lilies which recent explorations of Upper Burmah have brought to light. Its nearest allies are *Lilium Nepalense*, recently figured in the *Magazine*, and *Lilium Bakerianum*. The plant is described as producing a glabrous stiffly erect stem four feet long from a globose bulb two inches in diameter with small lanceolate scales. The leaves are numerous, scattered, sessile, linear, spreading, and two or three inches long. The flowers, which are borne on long peduncles

furnished with a linear leaf at the middle, are produced in about three-flowered corymbose umbels; they are funnel-shaped, three or four inches long, the expanded limb three inches across, with oblong-lanceolate segments, those of the inner and outer rows nearly uniform, an inch broad in the middle, white, tinged with green on the outside, on the inside, white above, white, tinged with yellow-green, below, and covered, except in the centre, with minute claret-brown spots. This fine plant is named in honor of its introducers, Messrs. Hugh Low & Co., the well-known nurserymen, with whom it flowered in July of last year.

Restrepia striata (t. 7233), a curious Orchid from New Granada, interesting to botanists from its peculiar structure, but of little value from a horticultural point of view.

Lilium Grayii (t. 7234), a well-known plant, first gathered by Dr. Asa Gray in 1840 on Roan Mountain, in North Carolina, and first figured in one of the early numbers of this journal (i., 19, f. 4). The portrait in *The Botanical Magazine* represents dark red flowers, and was made from a plant which flowered at Kew during the summer of 1891,

Fig. 49.—*Asarum Crux-Andræ*.—See page 256.

although the flowers are usually bright yellow, like those of the ordinary form of the closely allied *Lilium Canadense*.

Pilocarpus pennatifolius (t. 7235), a small shrub of the Rue family, and a native of Brazil, with large unequally pinnate leaves and slender racemes, a foot in length, of small red-brown flowers. This handsome shrub was introduced into European gardens forty years ago by Libon as an ornamental plant. Much later it has been learned that it is one of the principal sources of the drug Jaborandi, used in Brazil as a sialogogue and diaphoretic. The parts used are the dried leaves, which leave in the mouth an aromatic, slightly bitter, warm taste, and contain a volatile oil and an alkaloid, also volatile, to which the name *pilocarpine* has been applied.

Didymocarpus lacunosa (t. 7236), a lovely little plant of the Gesneræa family, and a native of Penang, with intensely violet-blue nodding flowers, and a recent introduction of the Messrs. Veitch.

The Garden, in its issue of May 7th, contains colored plates of *Erica hyemalis*, figured for the first time in this journal a few weeks ago, and of its white variety.

Foreign Correspondence.

London Letter.

NORTH AMERICAN CYPRIPEDIUMS.—We have a beautiful display of these plants in the cool Orchid-house at Kew, for which we are indebted to the curator of the Harvard Botanic Gardens and to Mr. Allen. The roots, which were received last autumn, were planted in pans in peat soil, and placed in a cold frame for the winter, where they were kept well watered. As soon as the flower-buds pushed up, the plants were removed into a cool greenhouse, where they developed beautiful leaves and perfect, richly colored flowers. No plants have been more admired this spring than these pans of *C. spectabile*, *C. pubescens* and *C. acaule*, some of which bear seven flowers, while they have all lasted well. This method of treatment has been found perfectly satisfactory. In the open ground we have only moderate success with these beautiful plants. Some of our friends declare that these northern species of *Cypripedium* are prettier in flower than the highly-prized tropical species.

DISAS.—This genus is gradually growing in importance among popular garden Orchids. A few years ago we possessed only *D. grandiflora*, the Pride of Table Mountain; but we now have two other pretty-flowered and easily managed species in *D. racemosa* and *D. tripetaloides*, besides a hybrid named *D. Veitchii*, which was raised from *D. grandiflora* and *D. racemosa*, and which promises to be a first-rate garden plant. A fourth species of promise has lately been introduced from Madagascar, and flowered in England, *D. incarnata*, of Lindley, described by him in his *Genera and Species of Orchidaceous Plants* in 1838, but not introduced alive till now. It has fleshy, strap-shaped leaves nine inches to a foot long, and erect spikes of bright orange-red flowers, with yellow dorsal sepals. The plant thrives in a cool house, and the flowers last a long time. It may cross with the Cape species and yield something good in color.

ODONTOGLOSSUM PLATYCHEILUM is a new species, which recently flowered in the rich collection of Mr. R. J. Measures, Camber-

well, who purchased it among an odd lot of Orchids, from Mr. Lee, of Leatherhead, some years ago. Its habitat, therefore, is at present unknown. Mr. John Weathers, Assistant Secretary to the Royal Horticultural Society, has prepared a sketch of the plant with a description for the *Gardeners' Chronicle*, from which I quote the following: "Pseudo-bulbs ovoid, slightly compressed, ancipitous, monophyllous; leaves oblong lanceolate, 8 inches long, one inch broad; scape short, erect, two (or more?) flowered; pedicels one to two inches long; flowers one and a half to two inches in diameter; sepals oblong lanceolate, white, with blotches of chestnut-brown at the base, keeled; petals similar, but not keeled; lip clawed, with a broadly cordate reniform blade, undulated, pale rose, with scattered blotches of crimson-purple; crest bilobed; column creamy white, clavate. The flowers suggest *Brassia* rather than *Odontoglossum*."

CATTELYA VICTORIA REGINA.—Messrs. F. Sander & Co., the discoverers and introducers of this new *Cattleya*, exhibited a plant of it in flower at the last meeting of the Royal Horticultural Society, where it was awarded a first-class

certificate. As I have already pointed out, it resembles *C. amethystoglossa* in pseudo-bulb and foliage. The flowers are borne on erect spikes, strong pseudo-bulbs producing as many as twenty flowers on a spike; they are six inches in diameter, the sepals oblong lanceolate, the petals slightly broader and undulated, and the lips three-lobed, the central one spreading as in *C. Leopoldii*, the lateral ones folding over the column. The color is soft rosy crimson, with a bronzy metallic shade, especially on the young flowers, the front lobe of the lip being rich crimson. The flowers may be likened to those of *Lælia elegans*. A quantity of plants of this *Cattleya* were sold by auction in London to-day; they were in good condition, and realized from one to five guineas each for plants likely to grow.

LÆLIO-CATTELEYA PHÆBE.—This is a hybrid between *Cattleya Mossiæ* (female) and *Lælia cinnabarina*, which has been raised and flowered by Mr. N. C. Cookson, who exhibited it last week at the meeting of the Royal Horticultural Society, and obtained for it a first-class certificate. It is intermediate in character between the two parents, the color of the flowers being yellow, with a crimson labellum. Messrs. Veitch's *L. Hippolyta* was raised by them from the same species, but they made *L. cinnabarina* the seed-bearing parent.

LÆLIA LATONA was exhibited at the same meeting by Messrs. J. Veitch & Sons, and also was awarded a certificate. It is a hybrid between *L. cinnabarina* (female) and *L. purpurata*, and resembles the latter in habit and foliage, but is smaller, as also are the flowers, their color being deep yellow with a dark crimson labellum.

VEITCHS' MANUAL OF ORCHIDACEOUS PLANTS.—Part viii. of this most valuable contribution to Orchidology has recently been published. It contains synopses of the following genera: *Oncidium*, *Miltonia*, *Ada*, *Brassia*, *Gomezia*, *Ionopsis* and *Ornithocephalus*. As in the previous numbers, the authors have limited themselves to species known to be in cultivation and possessed of some claims to the notice of horticulturists. Maps showing the geographical distribution of the species are given, and, in addition to careful descriptions of the species and interesting historical information, there are also numerous illustrations representing the flowers of some of the most attractive kinds. In dealing with the genus *Oncidium* the authors had a task of some difficulty. There are upward of three hundred described species, a large proportion of which have been in cultivation, but owing to the "miffiness" of many species they have never become established in gardens. The number of species of *Oncidium* described by Messrs. Veitch is 114, and of these, as they point out, a great many cannot be kept in health in English gardens more than two or three years. The genus is rich in beautiful-flowered species, but many of them have this great drawback of bad behavior under artificial treatment. Of course, there are some kinds, such, for instance, as *O. flexuosum*, *O. Batemannianum*, *O. bracteatum*, *O. leucochilum* and *O. sphacelatum*, which are as happy in our plant-houses as is *Odontoglossum crispum*. The *Miltonias* are treated upon exhaustively, as they deserve to be, and *Brassia* also obtains a fair share of notice. The other genera are dealt with in the same careful, discriminative manner which characterizes the whole of the work published up to the present. I am informed that the book will be completed in about two more parts.

BULBOUS IRISES.—A lecture by Professor M. Foster on these plants was one of the chief attractions at the last meeting of the Royal Horticultural Society. The professor finds time to devote to the cultivation of a rich collection of Irises of all kinds in his garden at Cambridge, and he is now the acknowledged first authority on garden Irises in England. But he admits that he has only lately come to understand the bulbous section of the genus represented by *I. reticulata*, *I. xiphioides*, *I. alata*, *I. Sindjarensis*, etc., which are generally notoriously bad to keep in the garden if not properly managed. He recommended growers to

keep this section in a part of the garden by themselves, and to lift the bulbs in summer so as to get them thoroughly ripened by drought, planting them again in late autumn in rich soil. The plants, in fact, should be treated as the Dutch treat their Tulips, Hyacinths, etc., and then there is little difficulty in keeping them and getting them to flower freely. I have before stated that we have proved at Kew that this treatment is suitable for *I. Susiana* and its allies.

THE DANDELION AS A GARDEN-PLANT.—In a piece of semi-wild ground attached to Kew there are now some thousands of plants of the common Dandelion in full bloom. They are broad tufts of rich green leaves with from a dozen to twenty flower-heads springing from each tuft, each head two inches across and colored a rich golden-orange. I know nothing that flowers so early in the year that will compare with these Dandelions for richness of color, floriferousness and elegance. I therefore venture to recommend the common ubiquitous Dandelion as a first-rate plant for spring effect in the garden. I can imagine a few beds of well-cultivated plants nicely placed on the lawn, and glistening in the May sunshine like burnished gold, surpassing any yellow flowers possible out-of-doors in May. The Dandelion is capable of being turned to excellent account in the flower-garden. We have beds of Tulips, Hyacinths, Daffodils, etc., in April and May, but nothing like to, nor even so good as, these big-flowered golden-yellow Dandelions. The French know the value of this plant as a vegetable, and have grown it largely for the last twenty years. According to Monsieur Vilmorin, it was formerly gathered from the fields and meadows where it grows wild, but as it became an important article of commerce in Paris its systematic cultivation and improvement naturally followed, with the result that improved varieties have been raised and their cultivation is now largely practiced. The whole of the plant is used for salad, the leaves being, as a rule, blanched by covering them with pots, as in the treatment of Sea-kale. We do not know the Dandelion as a garden-vegetable in England, but it deserves a place as a "bedding" plant, on account of its beautiful flowers. If, instead of being common with us, it had been obtained from Japan or China or New Zealand, we should have recognized its beauty and fitness for the garden by using it extensively for spring effect. No doubt, it might be improved, or, at any rate, variety of form, size and shade of the flowers could be obtained by cultivation and selection, just as the French have obtained considerable variety in the leaves.

W. Watson.

Cultural Department.

Bulbous Irises.

PROFESSOR MICHAEL FOSTER, of Cambridge University, England, the highest authority on Irises, recently delivered a lecture on the bulbous section of the Genus, which will be published in full in the Proceedings of the Royal Horticultural Society. The lecture, from which we take the extracts which follow, was illustrated by living specimens of many of the species, and also by drawings borrowed from the Royal Gardens at Kew.

Iris Sisyrinchium is one of the most widespread, and is related to the bulbous Irises of South Africa. It is characterized by the bulb being wrapped in a kind of network; it has two narrow leaves, from between which the flower-spike ascends. The flowers open about midday, and close about four o'clock, three or four slightly fragrant flowers being borne upon each spike. It is not a great acquisition to the gardener, and is rather difficult to grow in England. It requires a very hot summer and severe baking, and the bulbs should be taken up and well dried each season.

I. reticulata has a bulb very similar to the foregoing, but the leaves are linear and have four sides. The one generally regarded as the type has violet flowers, but this form is very rare, and is never found among imported bulbs of this species. *I. reticulata Krelagei* is a purple variety. The segments are

smaller and broader, and it has not the odor possessed by the other. As this is very much more common, it might be regarded as the typical form, more especially because, if crosses are obtained between the generally accepted type and *Krelagei*, the seedlings will chiefly follow the characteristics of the latter. *I. reticulata purpurea* is more handsome than the variety *Krelagei*, and there is another small variety of this group called *Cyanea*. *I. Sophroniensis*, an early flowering species, *I. Danfordiæ*, with which *I. Bornmülleri* is synonymous, are also allied to *I. reticulata*, as is *I. Vartani*, an Iris growing in the neighborhood of Nazareth, and flowering in October and November. *I. Histrio*, generally accepted as a different species, is regarded as merely a variety of *I. reticulata*. The flowers are not of a uniform color, but are blotched with lilac on a paler ground. A variety called *Histrioides*, although differing in several respects from *I. Histrio*, is certainly of the same species as that variety, while there can be no doubt about its being a member of the *reticulata* group. An Iris very like *I. reticulata*, with similar bulb and the leaves somewhat the same, is *I. Bakeriana*. The flowers of all these are very beautiful. The plants require plenty of sun and a good loamy soil, which should be rather stiff. They are liable to the attacks of a fungus,

tana is a large one, and grows in the neighborhood of Tangiers. It has a resemblance to the English Iris, but is exceedingly difficult to grow. It blooms early, but it requires a very warm spring and must be dried up in summer.

The Juno group differs from the rest in that the ripe bulbs possess a number of fleshy roots and broad leaves. These roots disappear annually, but if the bulb does not produce a flower, they sometimes remain, because the nutriment contained therein is not drawn upon. *I. alata*, or *I. scorpioides*, is a form of this group having broad leaves. The outer segments of the flower have an ear-like projection in each side, and it has a well-formed crest. The bulb is covered with several coats. It may be grown in the open, south of London, perhaps, but it requires the shelter of a greenhouse in the Midland counties. It has large flowers with various markings, exceedingly fine and fragrant. *I. Persica* is a very beautiful little plant, with flowers possessing very characteristic markings. There are many varieties of this lately introduced. They will stand frost, but require roasting in summer. They should be lifted each year, and thoroughly dried.

I. Caucasia, with its greenish yellow flowers, is not a great acquisition in the garden, but there are several varieties that

Fig. 50.—White Oak (*Quercus alba*) at Shandy Hall, Maryland.—See page 254.

that will cause the bulbs gradually to decay if they are left in the ground. If lifted each year, the fungus is greatly checked.

I. Kolpakowskyana is closely allied to *I. reticulata*, has bulbs with netted coats, but the leaves are not similar; it has a very beautiful flower, and is difficult to cultivate. *I. Winkleri*, with blue flowers, is very similar to the above; the leaves are more or less linear, and the bulb is covered with membranes. It has a somewhat limited distribution in Europe.

I. xiphioides has blue, purple and white flowers in different varieties, but in none of them can any yellow be seen. It is sometimes called the Pyrenean Iris. *I. xiphioides* (the English Iris) requires a more damp situation than the Spanish form. Both are thoroughly hardy, and can be left to themselves to a great extent. The name (English Iris) originated through its being first brought to Bristol and afterward distributed to the different parts of Europe from the west of England. *I. filifolia* is an exceptionally handsome flower—a rich strong purple limb and orange signal. It is slightly allied to the Spanish Iris. It requires a thorough baking, and would be benefited by a little pinching in summer through want of rich soil. *I. Tingi-*

excel the type. One of these deserves the specific name of *Orchioides*, a variety that differs in many respects from the type. *I. Rosenbachiana*, also belonging to the Juno group, is characterized by the fall of the outer segments, its beautiful rich markings at the bottom of the fall, and possessing an exquisite signal. It blooms in February or March, before sending forth any leaves, and sometimes among the snow. It looks like a summer flower, its surroundings not being suitable to its rich color and refinement. In the different plants the color is exceedingly variable, but the form is fairly constant. Another, belonging to the same group, is *I. Fosteriana*, with foliage not so broad, and having less fleshy roots. It comes from Afghanistan. A handsome contrast is presented between the golden-yellow upright part of the flower and the purple fall; it does not take kindly to the English climate. *I. Sindjarensis* is fairly hardy, and grows as well in our gardens as any of this group; a very beautiful and fragrant species.

Some of the bulbous Irises are not strong in their struggles for life, and ought to be grown by themselves and treated with great care, for if left to fight their way among other plants, the result will be disastrous to them.

Rock-garden Notes.

ONE of the chief features of the rock-garden at this time is the Iceland Poppy (*Papaver nudicaule*). The plants of last year have stood the winter extremely well, and are covered with their beautiful yellow flowers. An abundant supply of young plants are coming up from self-sown seed. These will bloom during the summer when the old plants have exhausted themselves, and there will thus be flowers throughout the entire season. *P. nudicaule album* is a beautiful free-flowering variety with satiny white flowers. *P. nudicaule minimum* is distinct, the flowers being intense orange-scarlet. The flowers of these Poppies are about two and a half inches across, and are produced on peduncles from twelve to fifteen inches high. They are fugacious, which renders them worthless for cutting purposes, except those of *P. nudicaule*, which last for several days after they are cut.

From a botanical point of view, *P. nudicaule* and *P. alpinum* are one species. They are, however, distinct enough for gardening purposes to retain their specific names, and can easily be distinguished from one another. *P. nudicaule* has a larger and more robust growth, and the foliage is less divided. The Iceland Poppy should be planted in a fully exposed position in the rock-garden in well-drained, moderately rich and light soil. Seeds are freely produced, and young plants are easily obtained from seed. The plant is a native of the boreal regions of the Old World, and was introduced into cultivation in 1759.

Orobis vernus is one of the hardiest and certainly one of the most charming spring-flowering, herbaceous perennials. It blooms annually with great profusion, even when flowers of this class are scarce. It is a native of Switzerland and Germany, and was introduced into cultivation two hundred and fifty years ago. It rarely ever grows higher than a foot. The flowers are produced on nodding, axillary peduncles. At first they are purple and blue, with red veins, and the keel is tinted with green. As they become older, they merge into blue, so that a plant shows flowers in many different shades. The leaves are composed of two or three ovate-lanceolate, acuminate, shining leaflets. The stem is simple and flexuose. This plant does best in deep, rich, moist soil, and thrives in a shady or an exposed position. It seeds freely and may be propagated from seed or by the division of strong roots.

Omphalodes verna, or, as it is sometimes called, the Creeping Forget-me-not, is an old favorite in gardens, and was introduced from the south of Europe. It is one of the plants to be relied upon for planting in shady positions, and when established it soon spreads. A large clump is growing luxuriously under Pine-trees here, and it produces an abundance of beautiful blue flowers for several weeks. It belongs to the Borage family, and grows from six or eight inches high. The single flower is about half an inch across, and is borne on a few-flowered raceme, on erect stems, which emit stolons at their base. The radical leaves are ovate-cordate and the stem leaves are ovate-lanceolate. *O. verna* is increased by rooted runners in the spring, planted in a shady place, in good, sandy soil.

For the last week *Corydalis nobilis* has been very attractive in the rock-garden, and if the weather is favorable the flowers will last two weeks longer. It is a Siberian plant, and was brought into cultivation in the year 1783. Its habit and form are good, and it grows about one foot high. The flowers are pale yellow, tipped with green, and the spur is long and incurved at the point. The leaves are bipinnate, the segments wedge-shaped and cut at the top. The foliage is handsome, and is further beautified by the graceful habit of the whole compound leaf. It is well suited for the rock-garden, and should be planted in a rather sunny position in deep, light rich soil. It is propagated by division of the roots.

Anemone sylvestris, sometimes called the Snowdrop Anemone, is flowering profusely on a large mound in a rather shady position. This plant grows about one foot high, and well-grown specimens are very attractive. Although this plant is a very old inhabitant of English gardens, it is seldom seen in good condition in America. The flowers are solitary, pure white, about one inch and a half across when fully open, and their drooping habit adds much to their beauty. The leaves are three parted; the lower lobes are deeply divided and are pubescent beneath. It is a native of central Europe, and is perfectly hardy in this locality. It flowers better here on an elevated position in the rock-garden than it does in our borders. It is easily propagated from runners, which grow up around the old plants, or from seed.

Dicentra spectabilis is one of the best herbaceous perennials in cultivation. It was brought to England from China in 1846,

and was known then as *Dielytra spectabilis*. It thrives well either in the rock-garden or in the herbaceous border, but delights in a deep sandy soil. It is largely used for forcing in the spring, and for this purpose a large number of the plants are grown in Holland and Germany, and sent to this country in the fall. It is propagated by division of the roots in the fall.

Cambridge, Mass.

R. Cameron.

Roses.

IN order to secure a regular supply of Roses for cutting during summer and fall, preparation is necessary early in the season. For summer flowers, out-of-doors, Marie Van Houtte and Papa Gontier are excellent sorts, and produce a succession of handsome buds throughout the season. The miniature flowers of some of the Polyanthas also are useful, and those of Clothilde Soupert are notably so, this charming variety being, doubtless, one of the best of its class.

Where one has facilities for indoor planting, summer showers can do no damage, although it must be admitted that Roses under glass will require much more attention than others. For greenhouse-planting Marie Guillot is the best white, La France a satisfactory pink, and Pierre Guillot a good red, while Duchesse de Brabant and Souvenir d'un Ami will furnish a good supply of light pink flowers, though of somewhat inferior quality to those first mentioned.

The planting of the stock should not be delayed now, and as they will only require a depth of about three inches of soil on the bench it is not a laborious operation to prepare for. A thin shade on the glass will be of benefit to the young Roses and will prevent them from drying out too rapidly during the hot weather. A thin mulching of good manure will be beneficial as soon as the plants begin to grow, and abundant ventilation will be needed.

The month of June is the time to note the most satisfactory varieties for permanent planting outdoors and to prepare for increasing the collection for the following season. Dealers' lists are not always reliable in descriptions of new varieties; at least personal observation is more satisfactory. Many of the old varieties are fully equal and often superior to the new ones, although the inexperienced buyer would hardly suspect this when reading descriptions of the novelties.

Very little budding or grafting of Roses is now done in this country in comparison with the vast numbers of these plants produced here annually, though many thousands of such plants are sent from Europe each season. These are usually distributed by means of auction-sales in the large cities. The budded plants, however, seldom prove as satisfactory as strong and healthy plants on their own roots, and, besides, being more liable to be winter-killed, do not grow with the same vigor. Many of these imported plants are used by the florists as pot-plants in flower, but are not as strong as the plants grown in the south Atlantic states, and which are own-root plants. One of the most interesting questions among the growers of Roses for market is how to get rid of eel-worms. These almost invisible pests have been shown by Professor Halsted to be the cause of the so-called club-root among Roses, and, as the measure of prevention recommended is to roast all the soil for the Roses before planting, it becomes a very serious matter to a large grower.

Other remedies suggested are various liquids to be applied to the soil after planting. These appear of doubtful value, as the worms seem able to stand quite as much as the plants.

Holmesburg, Pa.

W. H. Taplin.

The Cultivation of Blackberries and Raspberries.

IT is not an agreeable sight, after a winter of heavy snows, to find our small-fruit gardens giving no promise of a crop for the year. Really this is unnecessary. My Raspberry-canecan have come through in almost perfect order; the loss from breaking is not one per cent. This is accomplished by tying the canes in bunches of three or four above or below a wire which extends along the row. The variety I mainly grow is Cuthbert, which does well in solid rows. These rows, before I learned to tie them, were often flattened to the ground under drifts. In the spring much labor was needed to put them in order. I adopted the plan of cutting low; but while the breakage was less, the crop was also diminished. I now grow canes five or six feet high, and tie them with stout, coarse hop-twine. Our only cultivation is in the spring, when the ground is mellowed as soon as possible, and kept mellowed until the cultivator will break the growing shoots too badly. After that nothing is done except to manure the ground in the fall. The object of running the cultivator closely in spring is not so much to de-

stroy weeds as to cut up the sprouting bushes and throw all the strength of the new growth into canes in the rows. If left alone the ground between rows would be absolutely filled with young shoots. In spite of the cultivator, I am obliged in the fall to dig out superfluous canes. These are heeled in till spring, and then sold. Every grower of small fruits should have his surplus bushes and vines in shape to be disposed of at some profit. Until last year I grew my Raspberries even higher than at present, and the advantage was in shading the ground, as well as making it more convenient to pick; but I have changed my plan somewhat because the tendency was to shade too heavily the young shoots and weaken canes. The walls of berries presented on solid rows of canes tied as described is a picture.

In growing Blackberries we are compelled to take into consideration the style of growth; for some of our standard varieties send up invariably erect canes with few side shoots, while others are spreading and sprawling. Of the former kind are Snyder and Wachussetts; of the latter, Minnewaska; and between the two Erie, Agawam and Taylor. There is a decided advantage in the upright growers if you insist on cultivating between the rows. But this, after the berries have taken full possession of the soil, I abandon. They will smother weeds and grass, and no hoeing is necessary. After the second year I do nothing but cut out dead canes and shorten the tops, either in the fall or spring. The main point with Blackberries is the soil. This, if possible, should be cool, loamy and rich; but I never allow any application of barn manure. Fertilize with soil, rotted chip soil, or whatever will mulch and cool the soil. Our chief danger with Blackberries is a dry spell when the berries are approaching maturity. Of the berries now in cultivation, my choice for quality is Taylor and Agawam. Erie has not killed back this winter as it sometimes does; but it is not with me a good cropper of fine berries. Snyder is always reliable, but of moderate quality. Wilson, Jr., I see is still spoken of by some as hardy, but here it is hopelessly a failure. It kills down always, and even in the winters when peach-buds escape. Kittatinny is a noble fruit, and I get a crop from a small field by bending down the canes. Wachussetts Thornless does not differ largely from Snyder, and is entirely hardy. Few berries are badly affected by dry weather. On the whole, the key to success is cool, moist soil, not wet. If planted on high land, either mulching must be resorted to or frequent use of the cultivator. The Lucretia Dewberry is tender and must be laid down for winter and covered with leaves. In the spring I lift mine and tie to trellises. It will not pay to plant large fields. The demand for the Dewberry is, however, unlimited, but few persons are willing to incur the labor of cultivating it. The fruit is enormously large, very rich, and two weeks earlier than the high Blackberries. It will not ship to a distant market.

Insecticides and Fungicides in the Orchard.

PERHAPS I am too conservative for this progressive age, but I cannot help thinking that we are doing more spraying in our orchards now than we shall do ten years hence. There has rarely been any great scarcity of tree fruits in this country that spraying would obviate. It certainly could not have given the country a generally good crop of apples in 1890, and when there is a good blooming and the fruit sets freely, we have enough, and sometimes a good deal more than enough, as we had last year. In the off-years it will probably pay to spray our apple orchards, but in a plentiful one it would be better if we knew a good way to greatly reduce the fruitage of our trees, by a simpler method than thinning it by hand. I had all the fruit my trees would carry in 1890, being one of the few lucky ones, and I am still thankful to the Codlin-moth for the help she gave me in causing a large proportion of it to drop prematurely. I have never yet felt sure that this moth is, on the whole, a serious enemy to the careful fruit-grower. I am inclined to think that a light crop, occasionally, is a benefit to the trees as well as the market.

So much for the Codlin-moth. Spraying has no effect upon the Railroad-worm, *Trypeta pomonella*. As for the leaf and fruit fungus that causes spotting, I think the quicker we uproot every variety subject thereto, the better for us all. There are enough good sorts that do not spot, and some careful work in crossing the resisting sorts upon the best of the valuable spotting sorts, will give us practically many non-spotting duplicates. Such a duplicate, with me at least, is the Shiawassie, in place of the Fameuse. Scarcely one of the

Russian Apples is subject to this disfigurement, and by free crossing with resistant varieties we can keep clear of spot altogether. What, then, is the use of planting out these spotting varieties, when we already have so many kinds that do not spot? Spotting and cracking of our varieties of apple and pear are simply indications of a weak constitution or an imperfect adaptation to our soil or climate. We have been compelled, on this eastern slope of America, to plant the tree fruits of the western slope of Europe. It is no way surprising that many of them prove illy adapted to our climatic conditions. The severe winters and torrid summers of eastern America would be far better suited to the fruits of like latitudes from eastern Asia. Perhaps crosses between the two would be equally good; no one knows that they would not be even better. It remains a most astonishing thing to me, that the efforts to introduce these eastern European and Asiatic tree-fruits to eastern America are looked upon so indifferently, and even so scornfully, by most of our expert fruit growers, and by the great nursery firms. We have, on the western slope of our own continent, abundant proof that many of the fruits of western Europe are much more at home there than in our eastern states. The vines of western Europe have never succeeded in eastern America. The same is true of Apricots from that region, but varieties of all these fruits are growing successfully in eastern Asia, that, by all analogy, ought to suit us much better and give us more satisfactory results than we now have. True, in our middle states, the Pears, Peaches, Plums, Cherries and Apples of our transatlantic neighbors—or a sufficient number of them or of their American seedlings—are doing tolerably well, though rarely so well as in their old home. But, even where these fruits succeed, the trees are shorter-lived than the same varieties are in Europe, showing that they are not thoroughly at home with us. In fact, most of our popular and profitable varieties of Apples, Plums and Cherries, and even of our Pears, are seedlings grown in this country, and presumably a step or more on the road toward gradual acclimation to our conditions. Why adhere to a weak type when a stronger is at hand? It may be said that the Asiatic varieties are not equal to the European. No one knows this to be true. It is as yet but a hasty and bold assumption of conservative minds. But, even if true, when we have secured the vigor we may soon add to it the desired quality, and I feel very sure that when we get stronger races of tree-fruits we shall not have to wait long for quality, while we shall have constitutions vastly in advance of the old stock, and consequently greater resistance to both insects and disease.

Newport, Vt.

T. H. Hoskins.

Some Vegetable Notes.

THE last week in May or first of June is a good time in this latitude to sow Tomato-seed for a late crop. Even if the early plants, by reason of an unusually favorable season, continue to produce fruit, it is, late in the season, very inferior to that produced as the first crop on a fresh lot of plants. For canning purposes this late crop is the best of the season.

The planting of succession crops of Snap Beans should be kept up, as fast as the plants of the last sowing fairly develop leaves, until August, and in this latitude until the middle of September.

Salsify-seed sown the last of the month or the first of June will generally be better than that sown early in spring. Here, July 1st is time enough, for if sown early it will run to seed at midsummer, or at least get a check that will injure the quality of the roots.

Succession crops of Sugar Corn should be planted up to July. In this climate it is almost impossible to have early sweet corn, on account of the ravages of the Boll-worm, so we have to be content with Adam's Early in June and early July. With late Sugar Corn it is different, and we have fine ears of Stowell's Evergreen and Mammoth. Late in May is a good time to plant it, with successive plantings every two weeks until the latter part of July.

Musk-melons may still be planted. For family use we prefer the Emerald Gem, but the city-market buyers, who buy by eye mainly, will take the coarse Hackensack and even worse ones in preference.

Plants of Fottler's Brunswick Cabbage, set now, will make a fine succession crop to the Wakefield and Early Summer.

It is not yet too late to plant Okra. Aside from its value as an ingredient in soup, this is a delicious vegetable boiled and served like asparagus. It is not well to plant it too early, as it is quite sensitive to the weather, and will do better, starting after the ground has become warm.

In the south, the last of May is the best time to sow seed for

the main crop of Celery. The chief difficulty is to get the plants up at this season, and when only a few are needed, it is much better to get them grown in the north, where many plant-growers make growing of Celery-plants for southern trade a specialty. The small plants can be got in June and set a few inches apart in a cold frame, and protected by a lath screen instead of a sash.

About the first of June is a good time to put in a crop of Carrots for fall and winter use. The intermediate forms are best; the large, coarse sorts are only fit for cattle feeding.

Sugar Beets when about half-grown are good for table-use. The color looks odd, but the quality is all right so long as the roots are not overgrown. The seed may be sown any time up to the middle of June.

W. F. Massey.

The Forest.

Forest Experiment Station at Santa Monica.

IN no other state of the Union are questions pertaining to forestry of more profound importance than in California. The immense bodies of timbered land in the north, the comparative treelessness of the south, and the supreme need of preserving every drop of water in all parts of the state for irrigation, give an unusual interest to every effort directed either toward the preservation of the forests we already have or to the plantation of new ones.

The work of the State Board of Forestry, though hampered by an insufficient appropriation of funds, and somewhat, also, by the usual considerations of practical politics, represents, nevertheless, a very creditable beginning of a movement which has already shown the wisdom and foresight of those who inaugurated it, and is sure to have a wide influence on the future development of the state.

One of the best-directed and most promising undertakings of the Board has been the establishment of two experiment stations, one at Chico, in the north, upon land donated by ex-Governor Bidwell; the other in the south, at Santa Monica, upon land given by Senator Jones, of Nevada and his partner, who own together some 40,000 acres of beautiful and fertile land between Los Angeles and the sea. This station comprises twelve acres, situated within half a mile of the Pacific, and includes a narrow valley with its sturdy little stream, and two benches of a few acres each, which form steps to the level table-land above, and give a desirable variety of soil and exposure. The work here is, of course, turned more particularly to the growing of such trees as are expected to be specially adapted to the southern part of the state. A large proportion of the trees are of Australian origin, and interest is centred chiefly in the two wonderful genera, Eucalyptus and Acacia, the Gums and Wattles, as they are known in Australia.

It was recently predicted by an eminent German forester, Dr. H. Mayr (GARDEN AND FOREST, vol. iii., p. 445), that in fifty years it would be inconceivable that southern California was once treeless. "Amid magnificent forests," said he, "of Australian Eucalyptus and Acacias, the visitor will be inclined to doubt that he is really in America."

Many thousand young seedlings are grown annually for gratuitous distribution, and the grounds of the station are being filled with specimen trees and with small plantations set out in various ways to test the practical value of the different methods of planting and culture. Of Gums there are some forty species represented by trees from two to three years old, and from five to thirty feet in height, which are now at the most interesting stage of growth. Eucalypts, as a rule, have a great diversity of appearance during the first two or three years of their life. The leaves and habit change as the trees grow older, and assume, to a large extent, the same general character of long, pendant, lanceolate, and more or less glaucous leaves and drooping branches, so that in old trees it is often very difficult to determine the species except by the flowers and seed-vessels. Many of the trees at Santa Monica now have both their youthful and mature forms of foliage, and many are beginning to flower—a precocity certainly remarkable in trees which grow to such an immense size.

The foremost of the Eucalypti as regards the number grown in California is the *E. globulus*. The cultivation of this species has passed the experimental stage, since it is grown by nurserymen by millions annually, and is planted throughout the state, sometimes in groves quite large enough to be called forests. The extremely rapid growth of this tree, and the high price of fuel, make it a profitable investment for planting. A

tree of this species, recently cut at Santa Barbara, three years and nine months old from the seed, measured forty-three feet ten inches in height and eight and three-quarter inches in diameter at the butt. This tree was not an isolated specimen, but was in the midst of a grove planted eight feet apart each way.

The Red Gum (*E. rostrata*) is also established in California. Its growth is less rapid than that of the Blue Gum (*E. globulus*), but its lumber is more valuable. The wood is stronger, more easily worked, and more durable for such uses as posts, telegraph-poles, railroad-ties, and especially for piles, since it is not attacked by the Teredo.

Aside from these two species, but few of the many excellent Eucalypts were generally known here until brought into popular notice by the efforts of the State Board of Forestry. There have now been distributed through the state from Santa Monica a large number of new species worthy of attention for the different qualities they possess. Specimens of these at the station are already large enough to show indications of their value, and to give some useful hints to those desiring to plant.

Among the more noteworthy is the Sugar Gum (*E. corynocalyx*), a tree of rapid growth and handsome appearance. It is more umbrageous than most Gums, and produces a hard, strong wood, remarkable for its durability under ground. The chief merit of this tree, however, is its adaptability to the most arid localities. It has been recommended by Baron von Müller for planting in the Algerian regions of the Sahara, and has succeeded well in southern California on dry and rocky foot-hills impossible to cultivate. A specimen of this species grew during its second year from planting from eight and a half to nineteen feet in height.

E. viminalis, the Manna Gum, is one of the hardiest species, and has been extensively distributed to the cooler districts of the state. It will stand for a short time without injury, according to Monsieur Naudin, a temperature as low as fourteen degrees, Fahrenheit. Though a shapely tree for avenue-planting, and almost as rapid in growth as *E. globulus*, its wood is softer and less valuable than that of many other species. The custom is almost universal among the nurserymen here to sell this tree as *E. rostrata*.

E. marginata, the Yarrah, which is famous for the resistance of its wood to attacks of the Teredo when used for piling, and which forms such extensive and valuable forests in west Australia, has proved of rather slow growth at Santa Monica. Its increase in height does not exceed two or three feet in a year.

The station has a number of fine specimens of *E. amygdalina* and *E. diversicolor*, trees which, in their native soil, according to Von Müller, sometimes grow to a height of over four hundred feet, overtopping, perhaps, our giant Sequoias.

The handsomest of all the species at Santa Monica, at least in their present stage of growth, is *E. polyanthema*, or Gray Box. Its upright form and dense foliage at once distinguish it, but its chief beauty is in the delicate pearly gray color of the leaves, which, in the young growth, is almost lavender. On young trees the leaves are nearly round, and are gracefully curved. While not growing so rapidly as some others of the genus, the Gray Box produces very valuable timber, and has shown a capacity to resist extreme drought.

Next in order of interest to the experiments with the Gums are those which have been made with the Wattles, or Acacias. The Black Wattle (*Acacia decurrens*) is a specially noteworthy tree, as remarkable for its wonderful rapidity of growth as for its extraordinary beauty. But its chief claim to attention is in the value of the bark for tanning leather. The Golden Wattle (*A. pycnantha*), though not growing quite as fast, produces a bark still richer in tanning qualities. Thoroughly dried specimens have frequently yielded to a chemical test over thirty-six per cent. of tannic acid. These trees promise to give to California a plentiful supply of tanning material. The bark of the Chestnut Oak already commands \$16.00 or \$17.00 per cord in San Francisco, and the supply has yearly to be obtained from less accessible places. The tanners of the Coast appreciate the importance of the subject, and have shown considerable interest in the experiments of the board looking toward the more extensive introduction of the Wattles. In Australia and New Zealand the cultivation of these trees is rapidly spreading, some plantations containing as many as 3,000 acres, and apparently giving satisfactory returns. The trees are ready to strip when from five to seven years old, and an acre containing 1,000 trees is expected to yield over five tons of bark, valued at \$35.00 or \$40.00 per ton. The wood of the Wattles is used in Australia for spokes, staves, etc., and it makes excellent fuel.

Both these trees are very floriferous, and when in flower are masses of yellow bloom, the fragrant little golden balls hanging in innumerable racemes from every part of the trees. The Black Wattle seems to possess about the same degree of hardness as *Eucalyptus globulus*. The Golden Wattle is more tender, but will do well in localities of extreme aridity, and is contented with a very poor soil. These trees being somewhat difficult to transplant, the experiment has been tried of planting the seed in cuttings of bamboo or cane four or five inches long, set up on end and filled with earth. One or two seeds are planted in each tube. When the trees are six or eight inches high they are easily transferred to the field, tube and all, without disturbing the roots, and the cuttings of bamboo are left to decay.

Another noteworthy tree is the Blackwood (*A. melanoxylon*). Its symmetrical shape, dense foliage and abundance of flowers make it a very desirable tree for avenue-planting, while the wood, much resembling that of the Black Walnut, is highly esteemed in Australia for cabinet-making. The Blackwood, like the Golden Wattle, belongs to the wonderful phyllodineous Acacias, no less interesting morphologically than they are curious to the most careless observer. The leaves on the young tree for the first few months are soft, feathery and bipinnate. The leaf-stalks soon begin to broaden and lengthen out, until at last they become the somewhat stiff, leathery phyllodia which form the foliage of the mature tree, though sometimes retaining upon their tips, for two or three years, remnants of the bipinnate leaves of their youth.

These are a few of the more important of the many interesting trees which are being brought to the attention of California planters by the experiments at Santa Monica. The station is in charge of Mr. Wm. S. Lyon, an accomplished botanist and an enthusiastic tester of trees, whose pen has, moreover, done much to bring about a proper public sentiment in regard to all questions relating to the forestry-interests of the state.

Recent Publications.

Traité des Arbres et Arbrisseaux, Forestiers, Industriels et d'Ornement, Cultivés ou Exploités en Europe et plus particulièrement en France, donnant la Description et l'Utilisation d'environ 1,800 espèces et 1,000 variétés. P. Mouillefert. Paris, Paul Klincksieck. 1891.

The object of this work, which is appearing in parts and which we should judge was about one-quarter finished, is to furnish a brief account of the trees and shrubs which grow spontaneously or are cultivated in Europe and principally in the territory of France. The author is a well-known and learned dendrologist and Professor of Sylviculture in the National School of Agriculture of Grignon, where a well-arranged arboretum is maintained under his direction.

The works of comprehensive scope devoted to the elucidation of cultivated ligneous plants which have previously appeared in the present century is that of Loiseleur, a French botanist, who published in its early years a classical treatise on trees and shrubs usually known as the *Nouveau Duhamel*, it being regarded as an enlargement and continuation of the *Traité* of Duhamel, the great French dendrologist of the eighteenth century (Loiseleur's work is in seven folio volumes, sumptuously illustrated with colored plates, and has become so rare and expensive that many cultivators of trees are prevented from consulting it); the exhaustive and indispensable *Arboretum et Fruiticetum Britannicum* of Loudon, published fifty years ago and before the introduction into gardens of many of the plants now cultivated, especially those of western North and South America, Mexico, Japan, Australia and New Zealand; and the *Dendrologie* of the German, C. Koch, published from 1869 to 1872, and exclusively devoted to an account of the woody plants cultivated in northern and central Europe. The time then had come in France for a comprehensive work on the subject which should include, besides the familiar trees and shrubs of the gardens of Paris and of the north of France, the innumerable forms of woody vegetation which have been brought from all the dry temperate and subtropical regions of the world into the gardens of Provence.

The plan of Professor Mouillefert's work, as explained by the author, who has devoted many years to preparing himself for his task, embraces a brief history of all the principal trees, native or exotic, found in Europe growing spontaneously in forests, in dendrological collections like those found in the botanic gardens of all European cities, and in public gardens and parks; and also of the shrubs most commonly cultivated in orangeries and greenhouses—that is to say, all woody plants cultivated in

forests and gardens. Of such plants the author estimates the number of species as from eighteen hundred to nineteen hundred with eight hundred or nine hundred varieties.

The systematic catalogue is prefaced by an introduction, containing a brief treatise on those departments of botany which must be understood in order that trees may be studied intelligently, to which is added a list of technical expressions used in the work and eleven plates illustrating the form of cells, the structure of tissues and of wood, the various forms of leaves, and the different sorts of inflorescences and of fruits. Coming to the catalogue itself we find that the history of each plant is composed of four principal parts. The first is devoted to the origin and the geographical range of the species; in the second the principal botanical characters which distinguish the species are given in simple language, the author wisely confining his descriptive matter to the essential or differential characters which may be relied on to distinguish a plant of the particular species from the best-known species or type of the genus, in this way avoiding needless repetitions and bringing out the salient characters of each plant. The third part treats of the soil and exposure best suited to develop the plant in question, with notes on methods of propagating it; and in the fourth part is set forth the nature of the products—that is, the wood, the fruit, the bark, etc.—with notes on its value from the ornamental or from a sylvicultural point of view. An atlas or thirty-two colored plates accompanies the work, illustrating representatives of the principal groups, each plate displaying as far as possible a branch in flower and in fruit, a flower with its principal organs, an entire fruit and a fruit in section, and the seed. Besides these colored plates, the work is further enriched by one hundred and eighty-nine plates, reproduced from photographs, made by the author, of cultivated trees in different parts of France. These usually represent trees without leaves that their appearance in winter may be made familiar.

On the whole, the treatment of the subject so far as the result of Professor Mouillefert's observations have been published is good, although, as is generally the case with botanists working with plants represented by cultivated individuals exclusively, the number of species in some genera is unnecessarily enlarged, and too much attention is often paid to ephemeral varieties of little morphological or horticultural value; and "book species," which would disappear in the course of a critical study of all the members of the genus in their wild state, are too frequently admitted, as is perhaps inevitable in a work of this character. But, after all, Professor Mouillefert does not pretend to present his readers with an exhaustive study of the wild types of all the trees and shrubs cultivated in Europe, and confines himself to a treatise on the cultivated plants themselves as they appear in French gardens. This he has so far succeeded in doing in an acceptable and most useful manner, and we can recommend his work to all persons familiar with French who occupy themselves for profit or for pleasure with the cultivation of woody plants.

Notes.

The Société Nationale d'Agriculture de France, at a recent meeting held in Paris, awarded its gold medal, stamped with the portrait of Olivier de Serres, to Professor Sargent's *Silva of North America*, now being published by Houghton, Mifflin & Co.

According to the *Zeitung*, of Cologne, the owner of a Cherry-tree, which stood upon a piece of ground required for the enlargement of the railroad station at the village of Niederlahnstein, was recently paid \$600 for the tree in addition to the value of the land, and accepted this sum only after a long contention, declaring that the tree was worth at least \$900.

In the mid-May issue of the *Revue Horticole* a portrait appears of *Deutzia parviflora*, the most beautiful species, perhaps, of the genus, one of the best hardy shrubs in cultivation, and a native of Manchuria. It has recently reached the gardens of western Europe as it now appears through the Arnold Arboretum, which received it many years ago from the Botanic Garden at St. Petersburg.

A correspondent sends us from Boston flowers of the double form of the beautiful Cuckoo-flower (*Cardamine pratensis*), which has recently been found near Woburn, in Massachusetts, where it has become naturalized and covers a considerable area. This plant, which is rare in the eastern states, is also a native of Europe, where the double-flowered form is said to be not uncommon.

The growers of Tuberoses in eastern North Carolina, who have been for some years supplying the market with these plants, are much discouraged by the decreased demand and low prices for their bulbs. It has been suggested that their soil and climate are remarkably adapted to the growth of Roman Hyacinth, Narcissus and Lily bulbs. The whole tribe of Narcissus, now imported in such quantities, can be grown there in great perfection.

Mr. H. J. Webber, the author of a *Catalogue of the Flora of Nebraska*, which was published in 1890, has since found cause to make some corrections in his list and to enlarge it considerably, and has therefore written an appendix, which has just been reprinted from the *Transactions of the Academy of Sciences of St. Louis*. It mentions 432 species, not hitherto reported, from Nebraska, making the whole flora of the state, as thus far known, to include 2,322 species and varieties.

Mr. Samuel B. Duryea, of Brooklyn, well known for his intelligent interest in the park system of that city, has recently presented to it a tract of eight acres, extending for more than five hundred feet along the water-front and adjacent to the proposed shore-road to Fort Hamilton, on condition that this driveway, which, when completed, should be one of the finest ocean-drives in the world, is at once laid out and constructed as provided for in a recent act of the Assembly.

In June, 1890, the alpine experimental garden on the Brocken, in the Hartz Mountains, had been planted with two hundred species of alpine and Arctic plants and Siberian and North American conifers. Late in the autumn of the same year it was found that only six of these species had perished, while a number, in this their first summer, had blossomed and borne fruit. The unusually heavy snow-fall of the winter of 1890-1891 did not decrease the list, and since then about two hundred additional species have been planted.

From experiments made at the agricultural station of the Maine State College it has been found that disturbing the roots of Cabbage in transplanting appears to have no marked effect on the size of the head, and that the best results are obtained by frequent transplanting. A good Cabbage has a short stem; the leaves placed close together with short petioles, thus leaving little open space about the stem. The blade should be large enough to extend more than half-way around the head, to avoid the soft spot often seen in the centre. Firm, solid heads are less subject to the attacks of the cabbage-worm than loose, open ones.

Gartenflora recommends the winter-feeding of birds by fruit-cultivators, as a means of decreasing the ravages of insects on their trees. In many parts of Austria, it says, at the approach of winter, a circle of evergreen-branches is formed by sticking their butts firmly in the earth. The ground within the circle is covered by boards, and then other branches are laid across, so as to form a light roof for the enclosure. Seeds, bread crumbs, etc., are scattered on the boards, and the birds, quickly finding their way to the food through the interstices of the evergreens, are protected against wind, snow and the attacks of animals, and in the spring are ready to pay their debt by vigorous assaults upon the insects of the orchard.

It is pleasant to find that in *Far and Near*, the excellent and interesting monthly journal which is edited in this city by Miss Chapin for the Association of Working Girls' Societies, frequent attention is paid to the way in which plants and flowers can augment the joy of existence, even among the toilers in large towns. A year ago this journal contained a wisely suggestive article on roof gardens—a subject which has since been brought to general attention in our daily papers, and in the current number for May we note a very good paper by Miss Newell, called the "Growth of Spring Flowers," which is a simple account of the manner in which plants awaken to life in the spring, illustrated by an analysis of the Violet, with directions how to examine its internal structure. Such readers as had heretofore admired only the more obvious beauty of flowers, without noticing their hidden charms of structure, or considering their manner of development, ought to be won to a new and deeper interest by this simple lesson, and it is to be hoped that the writer will continue her teaching in *Far and Near*, taking up other familiar flowers in their successive seasons.

A few of the gardens in the immediate neighborhood of Boston have been beautiful from the profuse flowering of the various forms of small Apple-trees which have been introduced into them principally through the agency of the Arnold Arboretum. It is surprising that these plants are not better known and more generally planted. When in flower no trees are more beauti-

ful; they are perfectly hardy, and flower freely every year; they improve with age, and are unattacked by disfiguring insects with the exception of Tent-caterpillars; they grow rapidly, and, once established, never fail to flower. Many of them, too, are beautiful in the autumn and winter, owing to the abundant and often showy fruit which covers their branches. The most desirable are forms of the widely distributed and polymorphous *Pyrus baccata*, a native of eastern and northern Asia, and of these forms the most beautiful, perhaps, is the plant sold in nurseries as *P. Malus floribunda*, a favorite in Japanese gardens, whence, some twenty years ago, it was introduced into Europe by Siebold. This plant is particularly beautiful before the flowers expand, as the flower-buds are bright red; when these open they disclose the white inner surface of the petals, which make a charming contrast with the red buds nearer the extremity of the branches. Other varieties produce pure white flowers, and the plant known in gardens as *P. Parkmanni* or *P. Halliana*, rosy pink semi-double flowers, which hang on long red stalks. Hardly less beautiful is the Chinese *P. spectabilis* with semi-double pink flowers, and the Siberian Crab (*P. prunifolia*), with white or rose colored flowers. These are followed by our native species, *P. coronaria*, the latest of all the Apples to bloom, and distinguished by the delicious fragrance of its large pink flowers. No garden of hardy plants in the northern states is complete without a collection of these little trees, which, to display their full beauty, require good soil and abundant space for the development of their spreading branches.

When the opinion was generally held that the Sugar-cane never produced seed, it was believed that the numerous varieties which existed in the world had originated by bud variation. Since the discovery, or rediscovery, of the seminal fertility of the cane it has been found that seedlings of recorded parentage show in most cases some characteristics of relationship to the parent stock; nevertheless the variation is wide, and there is no doubt, from what has been learned in the past few years, that the different varieties of cultivated cane have come from self-sown seeds which sprang up and produced plants which were unobserved during the first year or two of their growth. Of course, this tendency of seedlings to vary is the essential condition of possible improvement under cultivation, and undoubtedly the cane will now be improved under the hands of careful cultivators and breeders of new types. The process of selection, however, must be slow, because seedling canes take, as a rule, two years to mature. The cane flowers in the autumn, and the majority of the seedlings even of an early variety, will need fully twelve months before they can flower. In the botanical gardens of British Guiana, as we learn from a late report, seedlings have been produced with stalks not larger than a stout lead-pencil and weighing only two or three ounces each. On the other hand, the largest variety has grown to a height of more than twenty feet, with fifteen feet of clear cane to each mature stalk, each one weighing as many pounds—that is to say, each foot-length of cane averages a pound in weight, and the total weight of canes from one stool was at least 650 pounds. Some seeds of the smaller varieties show a remarkable tendency both to reversion and improvement. Seedlings from the same parent cane in the same season have yielded plants ranging from a stalk weighing but six ounces, when topped, to one weighing seventy-six pounds. This means that if these plants were set as usual, at the rate of 2,178 to the acre, the former would produce 817 pounds, while the latter would yield seventy-four tons.

The death of the Abbé Léon Provancher, in his seventy-second year, occurred not long ago. He was born at Becancour, in the Province of Quebec, in 1820, and for some years was the curé of Portneuf. Compelled by delicate health to retire from the active duties of his ministry, he settled at Cap Rouge, near Quebec, and devoted the remainder of his life to the study of natural science. In 1869 Provancher commenced the publication of the *Naturaliste Canadien*, of which twenty volumes appeared, and was then abandoned owing to the refusal of the Government of Quebec to continue the annual grant which had made its existence possible. Provancher, who published much on entomology, is known to botanists by an elementary treatise on that science, published in 1858, and by his *Flore Canadienne*, a comprehensive work, published in 1862. Later he began the publication of his *Fauna Entomologique du Canada*, of which three volumes were completed. His writings include also an account of a pilgrimage to Jerusalem, a journey in the West Indies, and treatises on agriculture. He was the author of many new species and genera of insects, particularly of Hymenoptera and Hemiptera.

The Beauty of Our Trees in Spring.

FOR three centuries the splendor of the autumn colors of the American forest has been a favorite theme with the writers on the beauties of nature. Little, however, has been said of the peculiar beauties of our trees in early spring, and probably few persons, except the elect who worship in the inner temple of nature, recognize the subtle charm of our woods at this season or realize the variety and harmony of the apparel which our trees put on to celebrate the return of the vernal season. Here at the north in no other month are trees more beautiful than in May, when more clearly, than later in the year, appears the contrast between a forest of many species grouped as nature alone knows how to blend various distinct forms and many distinct shades of colors in one harmonious whole, and forests like those of Europe composed of a few species only. In May, from the top of a New England hill, or better, from one of the high summits of the southern Alleghanies, over which is spread the most varied, luxuriant and magnificent collection of deciduous trees in the world, may be seen the American forest in its most charming aspect, the outlines of individual trees veiled, but not hidden, by the opening leaves, which vary on each species in tone and color. This first flush of woodland beauty lasts only a few days, but they are precious days to the lover of the forest and to the student of individual trees, for the one can delight his eyes and study the harmonies of nature, and the other learn of characters, as constant as the structure of flowers or fruit, which will aid him in distinguishing the different species, for each may be recognized in early spring by the appearance of the very young leaves or of the scales of the leaf-buds, which on many trees in unfolding lengthen and assume bright colors. This is the case with the Horse-chestnuts, with many Maples, with all the trees of the Rose family, especially the Plums, Cherries and Hawthorns, and with all the Hickories, whose bud-scales grow to a great size before falling.

The vernal parade is led by the Red Maple and the White Maple; it is, however, with brilliant flowers, and not with unfolding leaves, that these celebrate the coming of spring, and before the leaves of these two trees unfold their flowers have fallen, and the brilliant scarlet fruit of the Red Maple has grown to its full size. Certainly one of the most beautiful objects to be seen in our woods in early spring is a Red Maple covered with fruit, which varies in brilliancy on different individuals, and at the north sometimes suffers from frosts which destroy the flowers. In southern Arkansas, Louisiana and Texas, where a variety of this tree grows with large and brilliantly colored fruit which frosts rarely injure, in March the Red Maple growing among the broad-leaved evergreens, which are common in that part of the country, is seen at its best, making a note of color in the landscape, and a sensation on the mind which time does not dull.

In northern woods the Amelanchiers are conspicuous in early spring by the colors of their unfolding leaves; in one form these are red, in another silvery white, and their vernal beauty is increased by brilliant scarlet bud-scales and bracts and by the silky white hairs which clothe the young growth. Of the delicate beauty of the flowers of this tree it is not necessary to speak, for every one who walks abroad in early spring knows the white flowers of the Shad-bush, which in April and early May enliven the banks of swamps and upland woods all over eastern America. Not less beautiful, perhaps, although less conspicuous and less familiar to the unpracticed eye, is the opening of their leaf-buds, which precedes the unfolding of the flowers. Among smaller trees the red shoots and young leaves of the Stag-horn Sumach and the deep bronze-green of the unfolding leaves of the Sheep-berry (*Viburnum Lentago*) add variety and charm to road-sides and forest-copses. Every one knows the tender green of the young foliage of the Beech, the most delicately vernal green of the forest, but this tree is well worth careful examination in early spring, when the expanding bud-scales are brilliant in color and the lengthening shoots and unfolding leaves are covered with soft pale hairs.

But the Oaks, perhaps, will best repay study in early spring; they make up a large part of our eastern forest-growth, and it is their variety and the peculiarity of each species that gives the character to our forest-scenery. Each species in early spring is distinct in color and in tone, and it is by the blending of these elements into a composition of perfect harmony that Nature shows how pictures may be composed, and how variety within certain limits is necessary if the greatest beauty of the landscape is to be obtained.

The earliest of our northern Oaks to spread its foliage is the Red Oak; the young leaves are yellow-green, in tint not very unlike that of the Beech, and are half-grown before the opening of the flowers which during a week in May make the trees great yellow bouquets. Rather later the Black Oak unfolds its leaves; at first they are bright scarlet on their upper surface, the under surface being covered with a pale coat of white wool. The red color gradually fades, and at the end of a few days they are light yellow-green. It is the Black Oak that in spring gives the soft hazy appearance to upland Oak-woods, although at one period of their development the leaves of the White Oak are not very different in color; these when they appear are sometimes bright red and sometimes delicate gray or mouse color, although before the flowers, which open late, appear they are more than half-grown and soft light green. The young leaves of the Bur Oak are orange and those of the Chestnut Oaks are light green. The Bear Oak is one of the most beautiful of all our plants in spring; the leaves are red until they are half-grown and until after the appearance of the bright yellow flowers.

We cannot pretend to describe even in the briefest and most unsatisfactory manner the vernal beauty of all our trees, or do more now than mention the grace of the Birches at this season of the year, the tender yellow-green of

the Sassafras, the sturdy unfolding buds of the Hickories, the red tints spread over the leaves of the wild Cherries, the beauty of the vernal Hornbeam and Hop Hornbeam, of the late-flowering Maples, of the Ashes, the Locusts, the Elms and the Hackberry, or of the conifers of which each species signals the return of summer in its peculiar way. A volume might well be written on the vernal characters and beauties of the trees of eastern America, but all we can hope to do now is to point out a woodland path, where there is much to be seen and many things to learn for the man who knows how to see, in the belief that he who does not know trees in spring and has not watched the early stages of their yearly growth has lost one of the best pleasures of life and missed one of the benefits which we Americans have in living in a country of such varied, interesting and beautiful forests that the forests of all other temperate lands are in comparison tame and uninteresting.

A WRITER in *The London Field* discussing the attempts which have been made in recent years to introduce bulbous plants into the grassy slopes of the Royal Gardens at Kew, sensibly calls attention to the fact that, "in such a vast garden there are many opportunities of carrying out this excellent system, particularly where the branches of trees touch the ground. In every one of such cases some of the delightful early flowers might be in position, the sheltered ground around such trees being exactly what many bulbs delight in. Hitherto use has been made of popular flowers well known in gardens, but this system may enable us to use with effect beautiful flowers that have not been generally considered worthy of cultivation in gardens—flowers which perhaps looked at in the hand are not so attractive as Lilies or Daffodils, but which might furnish new effects when seen in quantity. We mean such flowers as the less showy sorts of the Star of Bethlehem, Gazea, and even Allium, Fritillaria, European Gladioli, Grape Hyacinths, which we find thrive freely in grass, and the species of wild Tulip which are rarely seen in all their force of color, and also some of the beautiful and less showy spring flowers which might be used more freely, such as the Snowflake, principally the spring variety; St. Bruno's Lily in the rich grass is delightful, and the Dog-tooth Violet, which thrives in grass, and which, however dwarfed and starved, is always beautiful. The contrast between short turf and the waving grass full of flowers will be delightful. In the hot days of spring, flowers so often pass quickly away that it is a great advantage not to have to disturb the whole garden for them, whereas in the grass they are not in the way, and in the wild garden one bulb may succeed another, which is not so easy in the regular garden."

Certainly there is no more delightful form of gardening than this, or one which can be more easily executed if proper care is taken in selecting the plants to be used and in planting them. The essential thing in wild-gardening is the selection of the plants. These must look as if they were or might be wild, that is, they must harmonize with their surroundings. A stately garden Tulip or a monstrous garden Hyacinth looks out of place if it is seen by a wild wood-walk or in a field of waving grass, just as a great double-flowered Pæony looks out of place anywhere but in a garden-border. For natural planting, wild forms, or forms which have suffered little change by cultivation, are essential, although it is perhaps our association of such garden-plants with trim beds or borders rather than any inherent unfitness in the plants themselves that makes them appear out of place outside the garden proper.

Grass must be cut even by the borders of the wood-walk, although the operation may be delayed perhaps until July, so that it is necessary to select plants to plant in the grass that ripen their foliage early in the season, unless it is proposed to replant them every year. The Snowdrop, and the Crocus, especially white and yellow flowered varieties, can be used to advan-

tage in this way. All the Narcissi look well in the grass, and ripen their foliage early, although the Poet's Narcissus appears to thrive in grass better than any of the yellow-flowered varieties, and is perhaps the best of all plants to use in this way. With it will bloom the Blue Bell or Wild Hyacinth (*Scilla nutans*), a charming plant with flowers which are sometimes pink or white as well as bright blue. Some of the small-flowered wild Tulips, like *Tulipa Persica*, look well in the grass, as does the Star of Bethlehem, which has become naturalized in some parts of the country, and the Grape Hyacinth. All the Buttercups are beautiful in the grass, and so are our native Iris if the ground is moist enough to insure their vigorous growth. The list of plants, however, which can be used in this way is not a very long one, although among our native plants there are probably a few that can be seen to their best advantage in this way, and we recall a bank from which the grass is cut every year in June for hay, on which the Cuckoo-flower (*Cardamine pratensis*) has held its own for years, and gradually spread over such an area that now its lovely pale lilac flowers make a brave show as they gradually unfold during the last two weeks of May.

Practical Forestry.

THE following account of an experiment in growing White Pines in Durham, New Hampshire, by the Hon. John D. Lyman, of Exeter, appeared in a recent number of *The American Cultivator*:

In the year 1870 I purchased the abandoned Pike Farm. Some two or three years afterward I noticed about an acre of little Pines growing very thickly upon the land. In their condition at that time they had no market value. Mr. I. P. Berry, the treasurer of Strafford County, who thinned these trees for me, said that the acre of land with the little Pines would not then have sold for \$3.00. The process of thinning out was commenced about eighteen years ago, and has been continued at various times since, but the growth has never been sufficiently thinned, and even now numbers 178 trees. I think there should not be over 100 trees at this stage of growth.

For the purpose of thinning I recently cut one of the smallest, most crowded and oldest trees. This tree had once lost its main top, which, of course, checked its growth for several years, and it has been so much crowded that during the past ten years its growth has been very slow. Yet this tree was seventy-seven and a half feet in height, measured thirteen inches across its stump, and nineteen inches in circumference fifty-seven feet from the ground. I measured the circumference of the trees four feet from the ground, standing nearest a straight line drawn through the centre of the lot, and found the average to be a little over forty inches. One tree standing on the edge, and not included in those which averaged forty inches in circumference, girdled seventy-four inches four feet from the ground. This one, of course, is "limby" on the side toward the cleared land.

As these Pines came up very thickly, they had no large, low limbs. Their small limbs died for quite a distance from the ground. Several years ago I removed these dead limbs, leaving none within about twelve feet of the ground. Not being able to secure a suitable saw in Boston, I had one made from a wood-saw, and at an outlay of about three cents a tree I have lately had these dead limbs taken off, say eighteen or twenty feet from the ground. My object is not to promote growth, but to prevent loose, black knots in the boards. I presume it is generally known that while the Pine-limb is alive the knot is of a reddish hue and secured fast to the wood, but after the limb dies the annual growth of the trunk pushes out over the dead limb, and this part of the knot is black and often so loose as to fall out and leave a hole in the board when sawed from the log. The difference in value between clear pine boards and those abounding in knots, and especially in black, loose knots and knot-holes, is well understood by those who buy and sell lumber. In my experiments I am attempting to grow good lumber, instead of knotty, cheap lumber.

The greatest number of rings (these generally correctly indicate the age of the tree) which I have ever found in any Pine in the clump of which I am writing was forty-five. This number of rings I found in the tree lately cut. As its height was seventy-seven and one-half feet, the annual gain in height was twenty and two-thirds inches, presuming the tree to be forty-five years of age.

The fencing, shingle stuff and small timber taken from this clump in the process of thinning have very liberally paid all expenses. Had this acre been left entirely to nature and nature's methods of growth, there would have been at this time some seventy cords of wood upon it, which for fuel would have paid little or nothing over operating expenses at present market values. The border trees, and a few others, would have made small timber or box boards of little value.

I have never seen the groves of trees set out by the wealthy Massachusetts amateurs, Mr. Fay, of Boston, and others, but I think they would have found their investments more profitable had they properly thinned their groves from time to time. Thinning requires judgment and experience. The scorching of the trees by the sudden admission of sunshine upon the tender bark is to be avoided. The danger from wind is to be guarded against. If the trees are too far apart they grow too "limby," and if left too close they grow too slim and too slowly.

One of the first points to be learned in order to grow a crop, whether of timber, corn, or any other, is the number of plants to the acre which will produce the best results. Thus, too many corn-plants give nubbins, or no ears at all; too many potato-stalks give small potatoes; too many tree-plants give poles instead of timber. Years ago, my idea was to have Pines for timber trees very thickly set when young, so as to prevent large lower limbs. This theory proves to be a correct one. I then thought to thin out many times until the trees were about forty-five years of age, and then to leave one hundred to the acre until they were about sixty years of age, when I expected the trees to average each the equivalent of five hundred feet of inch boards, or fifty thousand feet of inch lumber to the acre. I then proposed cutting the whole or thinning again. After years of observation, I think I was about right at that time, though perhaps eighty Pine-trees to the acre, at forty-five years of age, would prove more profitable than one hundred.

B. E. Fernow, Chief of the Forestry Division of the Department of Agriculture, in Official Bulletin No. 5 on Forestry, states that 270 is in general the right number of timber trees to stand to the acre 100 years for timber. If this theory is correct, I am far from right in practice. Pines take less room than Oaks and other branching trees. I have studied nature and her ways without avail if 270 White Pine-trees is the proper number to be grown to the acre for timber until a hundred years of age. I have with measuring-line traversed our forests, and carefully studied their growths, and have consulted many owners of forests and many lumber operators, who have hundreds of acres of Pine-trees, but I find not one of them confirming the theory of growing as many trees to the acre as is recommended by the Chief of the Forestry Division.

The White Pine (*Pinus Strobus*) a hundred years in growing should certainly make 1,000 feet of inch boards at the mill, and thus we should have 270,000 feet of inch lumber to the acre, or an average growth of 2,700 feet per acre each year of the hundred. This is far beyond any growth to be found in my section. In my experience while lumbering I never cut 100,000 feet board measure upon any one acre. Set in regular squares, 270 trees to the acre would stand a little over twelve and a half feet apart from centre to centre of trees. I can find no two Pines of considerable size and thriftiness standing thus near to each other, with any considerable number of live limbs on the sides facing each other. Nor can I find such a Pine surrounded by trees equally high, and only thirteen feet distant.

One of my last object-lessons in forestry from nature was in the grand old woods upon the agricultural college farm in Durham, New Hampshire. The land is good, at a very low altitude, and all the conditions are favorable for tree-growth which has been undisturbed for 140 to 150 years. Professor Pettee, of the college, selected, at my request, what he considered as good an acre of Pine-timber as the forest contained. Upon that measured acre we found 156 live trees and thirty-four dead ones, including those which had already died and fallen. Their circumference four feet from the ground varied from twenty-two to ninety-eight inches. Two of these 190 trees were Birches, two White Oaks, one Maple, ninety Hemlocks, while the balance were White Pines. The average circumference of the 190 trees four feet from the ground is fifty-four inches and a fraction. The clump of New Durham Pines belonging to me has more than half as much timber to the acre as has the acre at Durham College, and will, barring accidents, by the time the trees are one-half the age of the Durham trees, have not only more timber to the acre, but of better quality.

This shows the advantage of aiding nature in the production of timber, the same as in the production of other crops, and proves the profits of practical forestry. Why did the thirty-four trees on the Durham tract die? With very few exceptions, I have no doubt they were shaded to death by the other

trees, although there were only 190 trees to the acre. A Hemlock-tree will grow in the shade where a White Pine-tree will die, and hence I presume by mixing Hemlocks and White Pines, as is the case in Durham, more trees can be grown to the acre than there could be of White Pines alone.

[After the extracts which we have quoted from Mr. Lyman's article were in the form for printing we received a note from Mr. Fernow, expressing the hope that he may find time soon to give our readers his views on the growing space which is needed by forest-trees.—ED.]

May in West Virginia.

STILL the Roses tarry, though a few are opening here and there. The Ramanas Rose, *Rosa rugosa*, is an early bloomer, with large, showy, single flowers of a bright crimson. They are very fragrant. It is delightful to know that no insect finds its handsome foliage toothsome; this fact makes *R. rugosa* especially valuable in the shrubbery. Madame George Bruant, which is a beautiful White Rose of Tea and *Rugosa* parentage, does not possess the acidity of foliage which is the protection of the Ramanas Rose, and the slugs feed upon it unless deterred by copious doses of hellebore or slug-shot.

Cinnamon Roses are now rioting over the garden, mingling their fragrance with that of the Mock Oranges, Locust blooms and Yellow Lilies. *Valeriana officinalis*, or Mountain Heliotrope, as it is called in this neighborhood, grows freely in the Lily-beds and has a refreshing and quieting perfume. This may be only imagination, but it is true that different perfumes affect the nerves in various ways. Thus the odor of Mock Orange, or Philadelphia, is overpowering to many people whom the breath of Lilies-of-the-valley, of Heliotrope, and the delicate fragrance of Roses and Honeysuckle thrill with delight.

Staphylea Colchica has a very powerful perfume suggesting Orange-flowers. It makes a handsome bush with its small, trifoliate shining leaves and pure white blossoms succeeded by bladderly pads. This *Staphylia* is now blooming and is much later than its American relative, *S. trifolia*.

Scotch Broom is one of the most showy members of the Pulse family. To-day it is shining with bloom. The leaves are wet from a heavy shower, and standing in full sunshine, the whole plant sparkles joyously, fairly lighting up its corner of the shrubbery, and even surpassing the Laburnums, which are flowering very sparsely. *Coluteas* are also coming into bloom. The Pulse family has representatives that extend the blossoming season for these plants from May until late in the autumn. Perhaps the familiar Sweet Peas, with their wonderful capacity for improvement, are the general favorites, but there are many charming members of this family among annuals, herbaceous perennials, shrubs, vines and trees that are rarely seen in cultivation. One of these is the Yellow-wood, *Cladrastis lutea*. We are now enjoying the rapid and vigorous growth of a very small specimen of this beautiful tree planted six weeks ago, which greets us with new twigs and leaflets at every inspection. The *Cladrastis* is a native of Kentucky and the south, and has a compact head with a tendency to develop more on one side than the other, even when planted in the open and exposed on all sides to the sun. It has a very smooth bark and beautiful light green foliage, which turns to a warm yellow in the fall. It begins to bloom when small, and has hanging panicles of flowers, often a foot in length, cream-white and pleasantly fragrant.

Tulip-trees (*Liriodendron Tulipifera*) are now in bloom. They grow to enormous size. Our largest specimen girths nineteen feet four feet from the ground, and is as tall as our tallest Oaks. It is perfectly straight, and forms, with its four brothers, which are almost as large, a fine approach to the house, following, as they do, the line of the winding road. Just now they are busy marts for myriads of bees. Their profusion of green and orange Tulip-shaped blossoms, and their habit of standing out as they do in relief against the bright blue sky, make them worth coming miles to see. These are our largest trees, though we have one Oak which is nineteen feet in circumference, and many more of great size and unknown age.

Our most satisfactory Rose is a climber with Tea blood, and yet of vigorous growth and very profuse bloom. This is Madame Alfred Carrière. It has long outgrown the trellis, seven feet in height, which we thought ample when the Rose was planted five or six years ago. This Rose is large, well formed, double, delightfully fragrant, and is a beautiful cream color with rosy heart. It is hardy, and never receives the slightest protection and very little care, yet we find it hard to restrain it within due bounds. It is our favorite, though we

have many other Roses. Queen's Scarlet, Hermosa, Monsieur E. Y. Teas are now in bloom, and the old-fashioned Giant of Battles has a few flowers of glowing crimson.

Weigelas, Rhododendrons and Pæonies of the *Officinalis* type are our most showy May flowers. One great double Pæony is the color of the Giant of Battles Rose, and is magnificent at this time. I think it is *Pæonia officinalis rubra*.

Spiræa Cantoniensis, often called *S. Reevesiana*, is still very pretty, and so are the earliest *Deutzias* (*D. gracilis*). But it is for the Feast of Roses that the garden waits.

Rose Brake, West Va.

Danske Dandridge.

The Raisin Industry in California.

FROM a carefully prepared article by T. Goodman in the *Overland Monthly* for May, we make the following extracts:

The picking of raisin grapes requires more care, and is a slower operation than the gathering of other varieties. The clusters, cut from the vine carefully, one by one, all imperfections and bad berries trimmed off, are then arranged regularly on the trays, so that all will have a fair exposure to the sun. If heaped, or overlying each other in the least, the drying of the under bunches will be greatly retarded.

To make good raisins the grapes should undergo a kind of fermentation in the first stage of curing, which gives them a puffed appearance, and fills the air with a pleasant fragrance. From ninety to one hundred degrees in the shade is the temperature most favorable for this process. After the fermentation has ceased, and the grapes have taken on the shriveled appearance characteristic of raisins, the sun can do them no harm, however hot.

To facilitate the drying, and render it uniform, the trays are reversed after three or four days, in order that the trays to the northward may be exposed to the south. When the upper side has become well cured, which may be anywhere from a week to two weeks, the raisins are turned. The reverse side does not require as strong exposure as the other.

The total time of curing varies greatly—from ten days, or less, in hot weather, to a month or more under unfavorable conditions. Raisins cured in about fifteen days are the best.

When the bulk of the raisins is properly cured the work of taking them up is begun. For this purpose the trays are collected and piled in stacks of fifty or more, and sweat-boxes, each holding about one hundred pounds when filled, placed alongside them. Three grades are usually made—extra fine bunches for Dehesa, or Imperial Clusters; ordinary bunches for London Layers; and imperfect bunches and loose berries to be run through the stemmer. Bunches not sufficiently dried are laid on the trays and exposed to the sun again.

Those put in the sweat-boxes are never uniformly dried, some being overcured, and some not cured quite enough. To equalize them and soften the stems, which are very brittle when taken from the trays, they are placed in a cool room and allowed to remain for a certain period, during which the stems become flexible, and the undercured raisins impart their excess of moisture to the overdried ones, the operation resulting in a perfect uniformity throughout the whole mass, and a moist softness and elasticity to be gained by no other means. The raisins, at this stage, undergo some completing and crowning process, not fully understood, accompanied by the emission of a fragrance of indescribable richness. This equalizing—or sweating as it is commonly called—is one of the most essential operations in raisin-making, and it should last ten days at the very least. Haste to get the crop to market has led to a neglect of this necessary process, much to be regretted. Raisins are purposely overdried, taken directly from the field, steamed and packed immediately. A continuance of this practice will do incalculable harm to the raisin industry.

A few extensive growers pack their own crops, but the bulk of the packing is now done by establishments organized especially for the purpose. These ordinarily buy the raisins in the sweat-boxes, but in some instances they purchase the crop upon the vines, picking and curing it themselves. The packing-houses are mostly located in the towns. Some of them employ more than five hundred hands. Women and girls come to the town from all directions during the packing season, parties of them renting houses or living, gypsy-like, in tents. Earnings range from \$1.25 to \$3.00 a day.

The raisins are then pressed and slid into the packing-boxes. They are made in three sizes, quarter, half and whole boxes, holding respectively five, ten and twenty pounds. The last is always understood when speaking of a box of raisins, the others one-half and quarter boxes. The top layer is sur-

rounded with ornamental paper in addition to the plain white. The packer's label is placed over this, the printed cover nailed on, the edges nicely trimmed, and the box is ready for market.

Less care is required with loose raisins; and it is here that the greatest improvement has been made on the Spanish method of packing. A combined stemmer and grader has been perfected by which large quantities are handled with very little labor. The raisins are fed from a hopper into the space between a woven wire cylinder revolving within a larger cylinder of the same material, where they are broken from their stems; they then fall into a fanning-mill, by which the stems and dirt are blown away, after which they pass through a series of screens that grade them into as many different sizes as are desired. The better grades of loose raisins are packed in boxes with paper and labels, giving them an appearance nearly as attractive as that of layers; the inferior qualities are generally shipped in sacks.

The cost of labor prevents California from competing with Spain in some of the niceties of the raisin business. It would not pay us to trim and nurse the grapes upon the vines, in order to secure perfect bunches and large berries, nor to handle the clusters by the stems only. But with the exception of such fancy work, comparison with our great rival will be all in favor of California. Our grapes are more meaty and have a richer flavor, and our raisins are better cured, and will keep twice as long without deteriorating.

New or Little-known Plants.

Boltonia latisquama.

OF the small genus *Boltonia*, consisting of only three species, all confined to the territory of the United States, the most desirable as a garden-plant is *Boltonia latisquama*, of which a figure made from one of Mr. Faxon's drawings is published on page 271 of this issue.

Boltonia principally differs from *Aster* in the character of the appendix to the fruit or pappus, and, from the horticultural point of view, the plants of this genus are like tall loose-flowered perennial *Asters*.

Boltonia latisquama is a stout plant with thick striately angled stems, which attain a height of three or four feet, entire sessile leaves, which near the ground are large and broad and gradually decrease in size on the upper part of the stems, and broad, flat showy heads of flowers an inch and a half across with violet-blue ray-flowers.

It was discovered about thirty years ago, near the mouth of the Kansas River, by the late Dr. C. C. Parry, who sent it to the Botanic Garden at Cambridge, from whence it was distributed. In cultivation this handsome plant is very hardy and in good soil grows rapidly, soon forming broad clumps which in early autumn are covered with flowers. It is one of the best garden-plants of its class, and one of the most beautiful, hardy, tall-growing and late-flowering perennial plants in cultivation.

New Orchids.

RODRIGUEZIA LINDENI, Cogn.—Described as a new species, but in reality only a form of the ancient *R. pubescens* of Lindley, an elegant and very free-flowering little species.—*Journal des Orchidées*, iii., pp. 10, 12, fig. 1.

CIRRHOPE TALUM AMESIANUM, Rolfe.—A pretty little species, native of Dutch India, introduced by Messrs. Linden, of Brussels, with whom it has recently flowered. It produces umbels of six to ten flowers, the united lateral sepals being light rosy purple with yellowish white margins and apex, the rest of the flower being yellow except the brownish red lip, and the ciliæ of the sepals and petals.—*Lindenia*, t. 314.

STAUROPSIS WAROCQUEANA, Rolfe.—A very distinct species, introduced from New Guinea by Messrs. Linden, of Brussels, and flowered in the collection of Monsieur G. Warocqué, of Mariemont. It has a branching panicle, on which the numerous flowers are closely packed, their color light buff-yellow, with numerous light red-brown spots, and the lip white with some rosy spots.—*Lindenia*, t. 319.

Foreign Correspondence.

The Experiment Garden at Wisley in England.

ENGLAND is enriched with several gardens of hardy flowers, and among them is the garden formed a few years ago by Mr. G. F. Wilson, F.R.S., at Wisley, in the charming county of Surrey. This delightful garden was designed for the growth of hardy plants in general and Lilies in particular. It is called Oakwood, to distinguish it from the cottage garden and grounds that surround Mr. Wilson's principal residence, Heatherbank, on Weybridge Heath. Many enthusiasts in hardy flowers travel to Wisley to see this garden in Primrose or Lily time. Wisley is approached by a drive of six miles from Weybridge Heath through characteristic scenery, now in its freshest and most charming spring dress. Oakwood was formed out of an Oak-copse; the natural character of the place has been preserved, and the result is a wild, picturesque spot, brilliant with flowers from the season of Primroses until the last Lily has opened its blossoms in late October. Sixteen acres of ground are covered with plants, each kind grown in large patches, so that the individual character and beauty are shown to advantage. In this comparatively small area there are no great scenic effects, but through the clearings in the trees appear brave masses of color; at this season stretches of ground are blue with the lustrous flowers of *Gentiana acaulis*, that grows here very freely.

A visit to Wisley may be made at any season of the year, save the dead of winter, in the certain hope that it will prove profitable. At the entrance to the garden one of the most conspicuous features is a hedge of the Japanese Rose (*Rosa rugosa*); the plants were raised from seed, and now form a splendid hedge with their spiny and leafy growth. The crimson fruits make a show during the summer and autumn, and from June until late in the year a scattered succession of the varied colored fragrant flowers is maintained. This hedge is one of the finest we have seen, and is useful as well as beautiful. Changes are always being effected at Wisley, and the garden is ever presenting some new feature. This will be a year for the Kämpfer's Iris (*Iris Kämpferi*), the beautiful species that the Japanese hold dear. Mr. Wilson has planted no less than 3,000 examples in a field practically outside the garden, and the finest forms will be selected from these, as they flower, for the adornment of the margin of the pond. *I. Kämpferi* grows exceedingly well here, and in July it makes a delightful picture, large clumps being planted around the sides of the water, where they make a forest of luxuriant growth and bloom. It loves moisture, and does not mind even contact with the water, although it is often thought that this is fatal to the plant. The great point is to select flowers of good colors, as pure white or deep purple, many of the mottled and blotched flowers producing a poor effect. The season for this Iris and the several species and varieties of *Lilium* is perhaps the most suitable time at which to see Oakwood, although those who care for Primroses and Auriculas would choose the spring months. The Lily finds here a splendid home, with the best cultural treatment given to the bulbs; the result is superb growth, even of those kinds generally considered most troublesome and uncertain. The garden is occupied in part by Rhododendrons and other shrubs, and it is from their leafy undergrowth that the tall stems of the Lilies rise in profusion. On every hand there are Lilies, about half an acre or more being devoted to *L. auratum* and its varieties. The shrubs protect the shoots from frosts in early spring, and the soil that suits the Rhododendron agrees also with the Lily. Of course, many of the kinds are comparatively common, but for the choicer types Mr. Wilson has a series of bays, the sides of hurdles or furze to protect the stems from winds. Here *L. Browni* forms a magnificent clump and *L. giganteum* attains giant dimensions, the stems rising to nine feet in height or even more,

and carrying a large mass of flowers rising from the base of rich green luxuriant leafage. *L. Japonicum odorum* promises to bear a profusion of flowers this year. *L. Krameri*, perhaps the most troublesome of all Lilies to deal with, under these conditions gives a wealth of flowers of a lovely rose shade differing in tone in individuals. Except for *L. giganteum*, no manure is given—a point of importance, as manure does harm to the general class of Lilies rather than promotes vigor of growth and flower.

Every turn reveals some treasure; the sides of a ditch were gay at the time of our visit with groups of *Primula capitata*, the double King-cup or *Caltha* (*C. palustris flore pleno*) kissing the water with its double golden-yellow flowers. Christmas Roses seed about in the moist soil, and form splendid clumps, while Primroses attain great perfection of form. There are few English gardens in which the common Primrose and its many varieties are more finely represented. The old double crimson, a very rare form, was flowering freely, and at the entrance to the garden the sides of the walk were gay with flowers of the most delightful colors and superb form. They are planted against cool gray stone for contrast, and this intensifies greatly the orange and yellow shades. The varieties here are very different from the Primroses one sees in ordinary gardens and too often at exhibitions. There are no dead, dull colors, mauve or washed-out pink shades, but the colors are deep and clear. This exemplifies the great improvement that may be effected by choosing only the best forms and colors for seed. The crimson, pink, rose and intermediate shades are of intense depth, and large masses make a glorious picture of color. They are planted by the ditch and under the shade of trees, where they obtain moisture and are screened from the direct rays of the sun. Possibly the blue Primrose attracts most attention, as being a flower of unusual color. Mr. Wilson has been several years in bringing to perfection the hardy blue Primrose, and has succeeded in raising flowers that please the artistic sense of color. This flower must not be placed in the same category with the artificial green Carnation that Londoners wear in their button-holes, for the reason, we suppose, that it is something out of the common, but which is essentially inartistic. It is an outrage upon beautiful Carnations to water the plants with dye to produce the horrid metallic lustre. The blue Primrose, although blue is never found in the varieties of *P. vulgaris*, and is foreign to the flower, is of great beauty, as remarkably free as the common wilding, and the clumps nestling against the cool gray stones are certainly beautiful. It is scarcely correct to call them blue; they are not the same intense blue as the *Gentianella*, but rather of a purplish violet tone, set off with a small central eye of deep yellow. Mr. Wilson has raised several varieties, of which Oakwood Blue is the best. It is a lustrous cobalt color, intensified by the small yellow eye, and from the first experiments until the advent of this form we have a gradation of shades, each new one displaying an improvement in color. We may, therefore, in time expect a flower that will be a deeper blue even than Oakwood Blue. But it will not be easy to eclipse this famous type in form; the flowers are full, broad and of excellent shape. The remarks that we have made respecting the Primrose apply to the self or alpine Auriculas. They are as perfect as the art of man can make them, the colors strong and deep, and the shape of the flowers as perfect as the ardent florist can desire. The deep maroon shades are delightful, but we get many tones from brilliant rose to almost black, set off with body colors which provide a rich or suitable contrast. It is only by rigid selection that such results are attained, weeding out the pale sickly colors, and retaining the best to raise seedlings from. In this way the strain, as we call it in England, becomes freed from the miserable weakly trussed varieties of poor washy colors that are utterly useless for giving beauty to the garden, although, unfortunately, occasionally seen at exhibitions under distinctive names.

The most brilliant hardy plant in late spring and sum-

mer is the *Gentianella*, or *Gentiana acaulis*, which is allowed to spread out into large masses. Mr. Wilson has several varieties of it, and, to use his own words, "the gorgeous blue of the type, especially when grown in full sunshine, might make it seem that any change in color would be a step in the wrong direction, but in this case, as the varieties are all of delicate colors, no comparison is provoked." These forms of this familiar plant were collected by his son, Mr. Scott Wilson, on the Swiss Alps, one having pale azure-blue flowers, another white, touched lightly with delicate blue, and in the third form they are tinted with pinkish purple color, which is of a deeper shade on the reverse of the throat. In such a garden as this a host of things find a place, and in one cool, shady, moist spot, near stones, the *Soldanellas*, as *S. alpina* and *S. minima*, were growing into a perfect mat, thriving in the moist vegetable soil with great vigor. These are usually provokingly troublesome to grow, and it is a pleasure to see them in rude health. *Anemone Robinsoniana*, among the trees, was delightful, its delicate color being in charming agreement with the natural wildness of the surroundings, and in a sheltered corner several varieties of *Primula Sieboldi* were presenting gay masses of bloom. *P. Japonica*, already bursting into bloom, forms a perfect carpet of growth by the side of the ditch, and there are few nobler plants than this for forming bold clumps of foliage, enriched in the summer with showy spikes of flowers. There are several varieties, but we prefer the deep crimson, as more showy and effective than the delicately tinted types. *Muscari* vied with the *Gentianella* for creating a wealth of blue color, and it is when massed that the full beauty of such things is revealed. In late May one of the prettiest flowers was the *Angels' Tears*, or *Narcissus triandrus*, sometimes called the *Cyclamen-flowered Daffodil*, by reason of the shape of the flowers, which are not unlike those of a *Cyclamen*. It is grown in large colonies, the creamy white flowers carried gracefully on slender stems, and thrives with vigor in a warm situation and light soil. Near a large break of this *Narcissus* we saw a mass of the picturesque *Rubus phœnicolasius* tumbling over a hedge, and in the summer the effect of the clusters of scarlet fruit peeping out from their mossy calyx is interesting. Over Mr. Wilson's house, that stands on rising ground, and commands a view of lovely Surrey woodland, *Reve d'Or Rose* has thoroughly established itself, as has the delightful *Button-hole* variety, *William Allen Richardson*. The re-introduced *Shortia galacifolia*, whose appearance may be described as that of an enlarged *Soldanella*, is growing well in damp vegetable soil by the ditch-side, and this charming plant is likely to be much grown in England; the flowers are pure white, and the foliage of many shades of green and crimson.

Although Wisley is not a great place for trees, save the beautiful Oaks and Silver Birches that are the glory of the natural woodland, Mr. Wilson has planted many charming things, as *Prunus Pissardi* and the finest varieties of *Pyrus*. The deep chocolate leafage of *P. Pissardi* assumes a warm, rich purple-crimson as the season lengthens, and last year it produced an excellent crop of fruit, which is, however, hardly distinguishable from the foliage; it is not unpleasant to the taste, but would never, we should think, be grown for its excellence. The past two or three winters in England have been severe, and many of the tender shrubs, as *Veronica Traversi*, have been badly cut, but those that have survived show great vigor. It is interesting to note how curiously the frost affects plants. In one place a large bush is utterly killed, and another of the same kind a few yards away, and growing under the same conditions, remains untouched.

At Heatherbank and in the cottage-garden Mr. Wilson's interest in hardy flowers is everywhere manifest. At the side of the drive to the house, and in front of large banks of *Rhododendrons*, thriving clumps of the best varieties of *Lilium auratum* and *L. tigrinum* give pleasure. The plants failed by reason of the root-ridden ground through the

Rhododendrons, until the plan was hit upon of sinking casks in the ground, with the bottoms knocked out, and filling them up with good loamy soil. This kept out the roots of the shrubs, and the Lilies seem to increase in vigor each year, although they have been in position several seasons. The effect of these brave clumps of showy Lilies is very fine, the dark leafage of the shrubs throwing into bold relief the handsome flowers. In a clearing made in a wood Lilies have also been planted freely, and in the partial shade and in the soil and moist conditions surrounding them are the picture of health.

These few hasty notes upon a delightful English garden of hardy flowers will doubtless be read with interest by readers of *GARDEN AND FOREST*, many of whom have possibly visited Wisley to note for themselves Mr. Wilson's experiments. It is called an experimental garden, but this is a harsh word for acres of hardy plants, each allowed to grow its own sweet way and tell its own tale of beauty in foliage, habit and flower.

Hardy Narcissus.—I.

THE season of these spring-flowering bulbs commenced here about the 20th of April with *N. bicolor præcox* (Hartland). There were blossoms of this variety open seven days before any other. These were quickly followed by *Ard-Righ*, *Countess of Annesley*, *Golden Spur*, *Henry Irving* and *General Gordon*. All of these varieties are *Ajax* or *Trumpet Daffodils*, and they are also all yellow. With us these kinds came into flower in the order named. I learned after the bulbs of *Ard-Righ* were planted that "garden-soil kills them." *Ard-Righ*, *Leda*, and the white varieties, *N. Moschatus*, *N. cernuus pulcher*, *N. pallidus præcox* and *William Goldring*, require conditions different from those under which the rest of the family thrive. They are hardy; the trouble appears to be with their digestion, and rich soil seems too strong a diet. *N. Moschatus* is fast dwindling away. Next fall all these varieties will be planted among grass. The flowers of *N. cernuus pulcher* are very chaste and beautiful, as are those of *William Goldring*, which is later flowering than the other varieties of the section known as the *Swan's-neck Daffodils*. *Leda* was a complete failure; from the few bulbs planted not one perfect flower was produced. Of the *Ajax* varieties *Countess of Annesley* is the best with us; it is almost as early as *Ard-Righ* and *Golden Spur*, and has a much more expanded trumpet. It does remarkably well in ordinary garden-soil, and it has also the merit of being cheap. The old *N. trumpet maximus* is perhaps the richest-colored *Daffodil* grown, and is good in every way. Though not an early-flowering kind, it comes in with *Empress* and the best of the *Bicolors*. *N. rugilobus* is free-flowering and does well. Bulbs planted two seasons have this year produced five to seven flowers to a bulb. This variety resembles *Emperor*, but is smaller; the outer edge of the trumpet is beautifully set at right angles as if hammered out.

The *Saragossa Daffodil* is an early-flowering variety, but is much too dwarf for border-culture, the first showers bespattering the flowers as they scarcely reach more than three inches above the soil. It would be a good variety for pot-culture, owing to its earliness, and planted in a rock-garden it could be brought more on a level with the eye. This variety is of Spanish origin, and flowers freely. *King Umberto* is distinct from all others in having a deep yellow stripe down the centre of a paler yellow perianth; the trumpet is large; it is a desirable variety, though of no use for cut flowers. *Golden Plover*, *General Gordon* and *Emperor* may be called second-early varieties, as they flowered about May 1st. It is curious to note how differently plants behave in this climate from that in which they were grown for sale. *N. bicolor præcox* came first, but in regular order, but *N. muticus*, which was expected to be the last, was a very close second, and was in full bloom with the earliest kinds.

It was intended to have a nice lot of very late-flowering *bicolors*, and one hundred bulbs were planted. Our compensation lies in the fact that no two of the flowers were alike; some of the perianths were twisted, some were not, and the length of the rich yellow trumpet varied a good deal. All were alike in being cylindrical and cut off abruptly at the end. In this variety the flowers developed somewhat before the foliage, but next season they may behave differently. It is a very interesting kind to grow both on account of the shape and varia-

Fig. 51.—*Boltonia latistama*.—See page 268.

bility. The *N. Johnstoni* varieties are high-priced, and will probably never become popular even if cheap. Mr. Johnston once sent us a small importation direct of what he called *N. Johnstoni*. There are now several varieties of this type, and the kinds vary in themselves almost as much as between one

another. Mr. Johnston stated that the bulbs should be protected from frost, but they are quite hardy, and do well in the open ground. It is scarcely necessary, in this connection, to say much regarding Emperor, the finest yellow Trumpet kind we have. Our spring season has been one of exceptional dry-

ness, there having been only one slight shower during six weeks. The flowers have consequently lacked substance, and in some cases the coloring was deficient, more especially in the Leeds and Barri sections, where the cups are stained with orange in the normal coloring.

South Lancaster, Mass.

O.

The Rock-garden.

BEAUTIFUL effects may be secured by the use of rough stones and stumps in floral plantations, and a large variety of plants which continue attractive during the greater part of the year may be well grown in a carefully contrived rock-garden. Nearly all the dwarf plants ordinarily used in decorative gardening are suitable for the rock-garden, and by a judicious use of the materials employed in its construction suitable positions may be provided for the many choice plants that will not flourish in the general garden, or anywhere, indeed, but in such places as closely resemble the dry, almost barren characters of their native habitats. No form of horticultural art is more attractive and interesting, and the plants are generally inexpensive, though some rare kinds are difficult to duplicate.

The various species and varieties of the extensive genus *Narcissus* make desirable groups, as do the Snowdrops, Squills, Tulips and other early spring-flowering plants. The same may be said of the *Fritillarias*, of which there are many varieties. The spring Snowflake (*Leucoium vernum*) is now out of bloom, but its summer relative, *L. æstivum*, flowers freely in late May.

The red and yellow flowers of *Aquilegia Canadensis*, the Canadian Columbine, are very attractive, and the plant is one that takes kindly to any position short of the bare rock. It attains a height of about two feet in good soil, but its growth is much stunted where the earth is poor and scanty. It is a graceful plant, and flowers freely in any case, spreading rapidly by means of the seeds, which are annually ripened in large quantities.

Trillium grandiflorum lingers on, though the flowers are not so numerous as they were earlier in the season, and those that remain have become somewhat tinged with red. This Wood Lily is one of the most effective early-flowering plants for moist and shady situations, as at the foot of the rockery. Similar sites should be accorded the lesser Periwinkle (*Vinca minor*) and *Orobus vernus*. Both of these plants are in fine condition in May, and the *Vinca* rambles about over the rocks without the least regard to regularity. Its pretty blue flowers and deep green foliage are also serviceable in forming an exquisite mantle in places where the gloom is so dense that most other plants will not live. There is nothing better than *V. minor* for a shade plant, and where it fails experiments with other plants are generally futile. It is equally satisfactory in an open position.

Orobus vernus is a highly meritorious plant, and one that well deserves more attention than is usually given to it. It has been known to horticulturists for over two centuries, and although of easy culture, it has never been very common. A shady and rather dry position suits it best, and the soil should be loamy and of medium quality. It is about twelve inches in height, and of erect, compact growth. The numerous stems are furnished with light green, pinnate leaves, and the purplish pea-shaped flowers are borne profusely in racemes at the top throughout the spring months. It is a native of southern Europe, and easily propagated from seeds in spring, or by division of the roots in autumn.

The *Aubrietias* are very gay in dry, elevated crevices. They are all dwarf and of compact habit. The purple flowers of *A. deltoidea* are very pretty, as are those of *A. grandiflora*, which are lilac color and of larger size. *A. Græca* has an exceptionally trim appearance, and the flowers are of a rich reddish purple color and good size. The flowers of *A. Hendersoni* are of deep, rich purple color; those of *A. violacea* are somewhat paler. But the gem of the group is undoubtedly *A. Leichtlini*. It is extremely floriferous, and the blooms are large and of a bright rose hue. These plants are perfectly hardy, and require little attention when once thoroughly established. But with the exception of *A. violacea*, which seeds freely and is therefore easily increased, they are all difficult to propagate. The best method I know of is to divide the tufts very carefully after the flowering season, and plant the pieces in a frame, using light, rich soil. Shading will be found beneficial in very bright weather until growth is started, and water should be given when necessary. The new plants will be ready for their permanent places early in autumn, and will flower during the ensuing spring.

The evergreen Candytuft (*Iberis sempervirens*) is a mass of snowy bloom in May. It is a plant of somewhat shrubby character, about a foot high, and of thick, spreading growth.

At other times the dark green leaves have a peculiarly refreshing appearance, but now they are almost totally hidden by the sheet of flower-heads. It is quite a hardy plant and likes free exposure to sunshine. Cuttings of the young wood taken in summer afford the best means of propagation. These should be placed in sandy soil, and kept in the shade until rooted.

Scilla campanulata is in bloom now. The leaves are strap-shaped, decumbent and about a foot in length. The Hyacinth-like scape is erect, from twelve to fifteen inches high, bearing numerous drooping, bell-shaped flowers of pale blue color at the top. It requires good, sandy soil, and large masses give a charming effect in partial shade.

The Iceland Poppy (*Papaver nudicaule*) is extremely handsome in its various varieties, the flowers of which are either orange, white or yellow. The plant is dwarf, and forms dense tufts of pale green, finely cut leaves. The cup-shaped flowers are from two to three inches in diameter, and they are borne singly at the top of erect slender stems, which are from nine to eighteen inches high, and bare from base to extremity. This plant is a native of the northern parts of Europe, and stands through our severest winters wholly uninjured, provided it is given a sunny aspect, where water will speedily pass away from the roots. The plantations of this delightful Poppy should be renewed at least every third year, as the young plants are more certain to give satisfaction than those advanced in age. Seeds ripen freely, and from these an abundant stock of plants may be readily obtained by sowing early in spring. The plants thus raised will flower in late summer and the following autumn, and in both spring and autumn during succeeding years. The small brick-red or white flowers of the dwarf *P. alpinum* are interesting, but not nearly so beautiful as those of *P. nudicaule*, and they are insignificant beside those of the scarlet *P. orientale*, which will bloom a week hence.

Omphalodes verna, the creeping Forget-me-not, is another pleasing little shade-loving plant. It is a native of southern Europe, and was introduced into English gardens in 1633. The creeping stem is furnished with ovate leaves on petioles two or three inches long, and the intense blue, spreading flowers, with white starry eye, are about twice the size of an ordinary Forget-me-not, and are borne above in short racemes. Propagation is quickly effected by division, and the plant spreads rapidly where the soil is good and the situation favorable to its development. The pale blue flowers of *Myosotis sylvatica*, one of the true Forget-me-nots, are quite showy in masses at this season, and its white variety is also useful in the way of diversity. Although a perennial, it is best when treated as an annual. The seeds should be sown in autumn, keeping the plants under cover during the winter, and transferring them to the open in early spring.

The commoner plants in bloom include *Arabis alba*, *Armeria maritima*, *Corydalis nobilis* and *Dicentra spectabilis*. These are universal favorites, and need no description.

Cambridge, Mass.

M. Barker.

Garden Notes.

I AM now certain of a matter of great importance to small-fruit growers, namely, that the development of berries in the fall exhausts the canes for the next year's regular crop. 1891 was peculiar in showing all over our Raspberry-fields an effort to produce a second crop of fruit. I could pick a quart at any time in October, and had freezing weather held off two weeks longer there would have been several crates of red raspberries ripe at one time. These fruit-stalks should have been promptly pruned off. This could have been done in a few hours with hedge-shears or with fruit-clippers. Our Raspberry-canecan have this spring budded very slowly, and the ends of the stalks are devitalized. This was not due to cold weather, as the winter did no damage to more tender plants. The Cuthbert, with me, endures extreme weather.

The same result followed a large development of Strawberry-blossoms in the fall of 1888. I do not believe we can do better than to remove such flower-stalks with great promptitude. The fall-bearing Blackcaps are worthless for summer fruitage. I have carefully looked over my fields and in every case a hill that had a fall crop is worn out or dead. A fall-bearing berry is useless for market purposes, as there is no call for berries out of their season.

We had occasion to pull up a small Locust (*Robinia Pseud-acacia*) which had started in my greenhouse, and found on the roots a series of small tubercles. The next day we came on the same tuberculous growth on the roots of a clover, which was pulled from a Strawberry-bed. I had read the biological discovery that plants of the Leguminosæ family were able to extract nitrogen from the air, but had not so far associated the fact with these nodules. It is a matter of ex-

ceeding interest to farmers, and one easily verified, that all plants in this family are affected by a parasitic growth such as I have described. The disease is caused by a bacterium which assails the roots of the plant and then grows out into these very pretty nodules. Whereas many bacteria are injurious, if not fatal to life, this one adds a new and extraordinary power to the plant attacked, and it is enabled by some means not yet understood, but through this parasitic agency, to extract nitrogen from the air. With this explanation it is easy to understand why Clover increases land fertility instead of exhausting it, and why plowing under a crop of Clover-roots is of so much value to the land. Every root is a nitrogen extractor. Beans have the same power, and all other members of the family leguminosæ. It is very probable that this same power is added to the natural functions of some other plants, and the field of examination is extremely interesting. Our boys and girls should be taught biology, and especially in the departments of bacteriology and entomology.

E. P. Powell.

The Garden in May.

TOWARD the end of this usually fickle month, the ordinary suburban garden blossoms out with tender plants which until this time have been carefully housed or have been bought en masse of the florist. These plants, observation will show, have a look of pained surprise at being moved to unaccustomed quarters, and it will be early summer before they are in harmony with their surroundings. No garden is complete without some of the invaluable tender plants, yet it seems incredible that any one should depend entirely on them, as is so frequently the case. A good garden is one which has the best obtainable plants at all possible seasons, and the merits of the plants are quite distinct from their being tender or hardy. If a certain class of plants can only be had in the open in summer, it would seem folly to allow the garden to remain a barren waste during the other three seasons. To lovers of nature, among which gardeners are usually classed, often, it must be feared, incorrectly, the tender foliage of the spring-time is one of the greatest charms of the early year. A garden of hardy plants at that time is a continually changing study in form and coloring, even if the many beautiful flowers of the season are not considered. That they are not more generally grown is perhaps due to this class of plants being less freely offered by the trade, rather than to a want of appreciation of them. The average plant-buyer is dependent on catalogues for his garden lore, and the plantsman has a tradition that "there is no money in them."

Not to speak of bulbs and the various plants which have been mentioned in GARDEN AND FOREST as the season has advanced, there are countless plants which are available as permanent occupants of the border, to appear with their various attractions as the seasons advance. With tender plants made a secondary feature, and hardy plants and bulbs the main reliance, one has a garden which will give generally a minimum of care, with usually less expense, and, if well considered, it will prove much more interesting and attractive. To form such a garden requires judicious buying, and it is well at first to confine purchases to a few well-known families of plants, ordinarily such as are cultivated largely by hardy plantsmen, and can be had at a low price. For example, as I write, the most prominent plants in the garden are the Columbines and the hybrid or German Irises. Columbine-plants may be bought, but a collection of German seed, such as is sold by the florists, will, if planted now, give flowering plants next year in wonderful variety. Mostly beautiful flowers these are, and there are also some which it will be no hardship to lose. There is a great difference in effectiveness among the different varieties. If the grower finds that the kinds bought give him pleasure, there are many other species to be selected and grown. If not satisfactory, the tentative experiment has cost little, and has at least been paid for by the pleasure of anticipation. The rhizomes of German Irises may be bought of most plantsmen in great variety at a very reasonable price, and they rank among the handsomest of garden-flowers.

Irises are called "the poor man's Orchids." There are few Orchids with flowers as handsome as some of the best of the Irises, and they have, besides, a nobility and grace all their own. They increase rapidly by creeping rhizomes, and soon give great masses of flowers. There are an endless number of species of this family, with widely divergent flowers and habits, and if subjects difficult of cultivation are desired, Irises can furnish a fair number to test the ingenuity of the most patient gardener.

Oriental Poppies are just commencing to show color above their graceful Acanthus-like leaves. It is unnecessary to say to any one familiar with Oriental Poppies that they alone furnish a garden in their season, everything else paling before their vivid fires. To others it may be recommended as a desirable plant to be carefully placed. But a vision of Larkspurs, Campanulas, Foxgloves, Spiræas, Phloxes, Pæonies, Coreopsis, Grasses, etc., remind one of the wealth of hardy things to come before the Roses are fairly represented, though the Japanese Rose has already opened the season with its chastely beautiful flowers.

Elizabeth, N. J.

J. N. Gerard.

The Bachelor's Button.—Various plants are known under this common title of Bachelor's Button. The name is a very old one, having been in use over three hundred years ago, with particular reference to a double-flowered form of *Ranunculus acris*, the Golden Bachelor's Button. It is mentioned by Gerard in his famous Herbal, and that author attributes its origin to the resemblance which the flowers bear to the jagged clothes buttons formerly worn in Britain. Other writers, however, according to Dr. Prior, declare that a habit of country fellows to carry these flowers in their pockets to divine their success with their sweethearts, gave rise to it. The other plants to which the name is given may be distinguished as the White, the Red, or the Violet Bachelor's Button; the plants are botanically *Ranunculus aconitifolius flore pleno*, *Lychnis sylvestris* and *Scabiosa succisa*. The last two plants are scarcely known in gardens, nor are they desirable except as curiosities, since there are many other more beautiful species of the same genera now in cultivation. *Ranunculus acris*, the Buttercup, is already a common weed in many parts of the United States, having been naturalized from Europe. Its double form is a much-esteemed garden-plant, flowering in May and June, and like the species in everything but the flowers, which are extremely useful for cutting. It is easily grown, and looks well in either the border or the rockery. Propagation is effected by dividing the roots. The White Bachelor's Button is a plant of similar utility and requirements, and usually blooms about a month later.

Correspondence.

The Winter-killing of Conifers.

To the Editor of GARDEN AND FOREST:

Sir,—I have observed some correspondence in your journal as to the winter-killing of certain coniferous trees, and I am constrained to say that in the Arboretum few of the *Retinosporas* of any variety have escaped burning more or less. The *Arbor-vitæ* have suffered greatly, and I have been compelled to cut away more than half of the growth of many quite large specimens. Even the Red Cedar has suffered considerably, and I never saw young White Pines in a worse condition, even plants of considerable size being badly scalded. A great many of the Balsam Firs, which ought to be hardy enough here, are nearly dead. Up to the 1st of March these trees all looked well, and my opinion is that much of the damage was done by some very warm dry weather in April, with high drying winds, followed by several severe nights, when ice was formed an inch or more in thickness. *Genistas*, *Cytisus* and *Furze*, wherever they were covered, are in a pitiable condition, while others which were left to themselves have come through safely. *Daphne Genkwa*, which has always survived the winters here with a light covering of earth, has succumbed this season. The *Ligustrums*, with the exception of *L. Ibot* and *L. media*, a dwarf form from Japan, have been hurt considerably, while *Weigelas*, which usually winter-kill badly with us, are in prime condition, and show hardly a dead branch. The varieties of *Berberis vulgaris* have suffered, while *B. Thunbergii*, *B. Sieboldii*, *B. Amurensis* and others from Japan and China are in fine form. The *Cotoneasters*, which are usually a little tender, show no harm. It is difficult to find any theory which will account for vagaries like these.

Arnold Arboretum.

Jackson Dawson.

To the Editor of GARDEN AND FOREST:

Sir,—The article from Mr. H. H. Hunnewell in a recent number of GARDEN AND FOREST, relating to the loss of conifers, has been read with much interest in this vicinity, where the loss of fine evergreen trees and shrubs during the past season has been quite considerable. Mr. Hunnewell's broad experience and intelligent observation give his statements special value and interest.

At my own grounds some excellent specimens of *Retinopora squarrosa* and *R. filifera* were materially injured, and from observation in other places, the past season has been one of the worst in several years, for many kinds of conifers. The loss of good specimens of *Retinoporas* within fifty and one hundred miles of New York has been considerable. Pines, Spruces, etc., have fared better, and but few losses are to be noticed even among the Hemlocks and *Arbor-vitæ*, which frequently suffer most in unfavorable seasons in this locality.

Considering the large exposed foliage of *Rhododendrons*, these plants have suffered comparatively little, although specimen plants at some of the fine estates on the Hudson and other places have lost a part of their foliage. It is of advantage to arrange all this class of plants in masses in beds or borders, where the conditions are favorable for retaining moisture in summer and winter.

Mr. Hunnewell is fortunate in having the large specimens of the varieties of *Retinopora* and *Thuopsis* he mentions. Many consider these varieties less hardy than the more common evergreens. Such results in the severe climate of Wellesley indicate that the right treatment has been given, and that the right plants are in the right place.

It is generally considered that the cold weather and unfavorable winds of winter and spring are the main causes of the loss of most evergreens. If this is a popular fallacy, and we come to a better understanding of the importance of a normal condition of moisture during summer and autumn, it will be comparatively easy in many cases to adopt remedies to avoid the loss of these beautiful trees.

New York.

Fred. W. Kelsey.

The Waukegan Nurseries.

To the Editor of GARDEN AND FOREST:

Sir,—June has come, and it finds the Apple-blossoms here about just opening and the pink leaves of the White Oak no bigger than squirrels' feet. Rain fell two days out of every three in May, and practically there has been continuous wet weather since February, so that looking from the car-window a visitor sees water flowing in the furrow after the belated plow in one field, and the farmer in the next one planting corn in the mud. I rode out to Waukegan to see Robert Douglas, and found the veteran nurseryman in his overcoat. To an inquiry whether this was a fair sample of early June weather in Illinois, he replied that no spring so cold and wet had been experienced in this vicinity since 1844, which was the year when he drove out here in a buggy from the eastern slope of the Green Mountains. In mid-June then all the country was under water about Chicago, and in the young town itself a few wagons were moving through the streets, while many more were fast in the mud. He managed to find a place to sleep on the floor of a hotel, the earlier comers having preempted the dining-room tables, but his horse stood out all night tied to a post without a mouthful to eat, for the farmers could hardly get into town without swimming, and any attempt to haul oats or hay was out of the question. The next day he reached drier land, and he kept on through different depths of mire until he reached Waukegan, where his horse gave out, and left him stranded. Practically his home has been there ever since, although he is known to almost every one between the two oceans who is interested in arboriculture, and of the trees from nursery seedlings now standing in forest-plantations in the United States a greater number have been raised by him than by any other man; in fact, until within a few years more forest-tree seedlings were raised by him than by all other nurserymen combined.

When the Waukegan Nurseries were founded, nearly half a century ago, Ellwanger & Barry had recently established the Mount Hope Nurseries; but west of Rochester the only establishments of sufficient size to warrant the issue of a catalogue were those of Hodges, of Buffalo; Custed, of Cleveland, and Elliott, of the same city. Mr. Douglas began at the outset to raise seedlings for Apple and Pear stock, and although he was warned that he never could compete with imported Pear stock, he was soon sending large quantities of excellent material to the older American nurseries in the east. In 1863 he had fifty acres of Apple-seedlings, which he sold at a year old for \$8.00 a thousand. Meanwhile he had begun the pioneer work of raising deciduous forest-trees from seed, and for a long time he had little competition. In later years, however, these trees have been produced in enormous quantities on the cheap land farther west, and comparatively few species are now produced on a large scale at Waukegan. He still grows many Soft Maples and Elms and Birches for ornamental planting, and great blocks of Black Cherries, Catalpas, Green Ash and White Ash, for forest-planting.

The raising of coniferous trees from seed, however, requires special skill, and the production of these trees continues to be the leading specialty at Waukegan. After many experiments and some costly failures Mr. Douglas learned that the methods pursued in the Old World could not be trusted in our dry and hot climate, but he finally succeeded in securing proper conditions of shade and moisture by various devices, and especially by covering high frames with the leafy boughs of forest-trees, and since then his success has been assured. Constant watchfulness is required, since young seedlings remain sometimes as long as three years in the seed-bed before they are transplanted to the nursery rows, but the vigor of the trees raised here has been tested all over the country, and the luxuriant growth of the young trees now standing in the nursery bears witness to the intelligent and thorough way in which they are brought forward. White Pines are raised here by the million. The Red Pine is produced in smaller quantities, not because it is more difficult to grow, but because the demand for it is so limited. Buyers seem slow to recognize the superior merit of this tree, both for forest and ornamental planting. It requires greater care in starting, but it is worth all the trouble it costs, and the time must soon come when it will be very largely used not only for its beauty in parks and private grounds, but for its usefulness in forests. Special attention is devoted here to raising the hardy evergreens from the Colorado Mountains, particularly the Douglas Spruce, the Colorado Blue Spruce (*Picea pungens*) and the beautiful Fir, *Abies concolor*. Mr. Douglas was among the earliest to secure seeds of these trees, and collecting them as he does in regions where the winters are severe and the summers are dry, the seedlings prove perfectly hardy. Nothing can be more beautiful than the long stretches of *Picea pungens* which are standing at an even height of four and a half or five feet in the nursery rows. These trees give perfect satisfaction wherever they are used, and even in parts of Minnesota where the Box Elder and the Green Ash fail, they endure the winters without harm. The Douglas Spruce is a still more beautiful tree which is just beginning to be appreciated, and long rows of specimens, from six to eight feet high, already show its remarkably graceful habit and soft foliage. The White Spruce is another tree which is very largely grown, and it is much more satisfactory under many conditions than the Norway Spruce. All the hardy conifers, native and foreign, are grown here in quantities, and the scale on which this business is conducted can be seen from the fact that as many as five million seedling trees have been sold in a single year.

At different times we have given accounts of the forest-plantations which have been made by the firm of Douglas & Sons under special contract. Under these contracts the firm agrees not only to furnish the trees but to prepare the ground for them, to plant them four feet apart each way, and to take entire charge of the plantation for a number of years and deliver the forests to the owners after each acre contains a guaranteed number of trees of a given size which completely shade the ground. When the trees have reached this size it is assumed that they can hold their own against the encroachments of prairie-grass and weeds. The advantages of this arrangement are that the work of planting, as well as the care of the trees while they are young and feeble and need the most intelligent attention, is confided to trained hands. Very few people in the country have planted a hundred acres of forest-trees in a single body, but under this arrangement Mr. Douglas has planted many larger tracts, one or two of which cover a square mile in area. The firm has planted 3,000,000 Catalpa-trees in a single county of Kansas.

Of course, so close an observer as Mr. Douglas would find varieties of trees which have special merit, and some of the specialties of the Waukegan Nurseries, like the *Arbor-vitæ* known as Douglas' Little Gem, the Waukegan Trailing Juniper, the Golden *Arbor-vitæ* and a silver-tipped form of the same tree, are well known to planters. Of special interest just now is a large block of what Mr. Douglas calls the Large Cone Balsam. The original trees came from the Wolf River, in Wisconsin. Some of them, which have attained a height of some thirty feet, are standing on the beautiful lawn in front of Mr. Douglas' old place, and they are certainly splendid specimens. The lower limbs have not died away, as is usually the case with the common Balsam, but they are furnished fully to the ground. The leaves are longer and the cones are much larger, and they are so different from the common Balsam that they can be readily detected at a distance even in the seed-beds. Altogether, the tree is distinct and beautiful, and promises to be of great value in ornamental planting.

But, after all the treasures of the Waukegan Nurseries have

been studied, the visitor will find their highest interest centering in the personality of their founder. Mr. Douglas carries his eighty years so lightly that he seems to have discovered the fountain of perpetual youth, and he looks as fit to set out for California now as he was in 1849, when he started for the Pacific coast with an ox-team and, having lost them in a swollen river, tramped on foot to his journey's end. There are few parts of this country where the native trees have not been studied by his observing eyes, and his stores of practical knowledge in his specialty are almost inexhaustible. His memory retains impressions with remarkable tenacity, and his picturesque way of recounting the experiences of his long eventful life is a source of unending pleasure to all who meet him. Above all, his broad public spirit, his transparent honesty, his manliness and gentleness, command universal respect and affection.

Recent Publications.

Les Fleurs à Paris: Culture et Commerce. Par Philippe L. de Vilmorin. Paris, J. B. Ballière et Fils. 1892.

This little book will, at the very first sight, interest all growers of plants by reason of its author's name; for Monsieur Philippe de Vilmorin is not only the son of Monsieur Henri L. de Vilmorin, the learned and famous French horticulturist, but represents the fifth generation of the Vilmorin family which, in one or more of its members, has devoted itself to the culture of plants, and more than any other single family has raised French horticulture to its present high position.

His father, in a brief introduction, explains the origin of his book. About a year ago, it seems, Monsieur Henri de Vilmorin was asked by the French Association for the Advancement of Science to speak about "Cut Flowers" at one of the conferences which this association holds each winter in Paris. Afterward the Messrs. Ballière, publishers of the *Bibliothèque Scientifique Contemporaine*, asked him to elaborate the substance of his lecture, so that it might form a volume in this collection of useful popular manuals. But as other demands upon his time were too numerous he turned the task, together with his own materials, over to his eldest son, whose work now lies before us. The father asks the reader's indulgence on the ground that this is a maiden essay, published before the writer had entered his twenty-first year. But one does not feel that his plea needs to be insisted upon, for the young man has his full share of the widespread French aptitude for graceful literary expression; and, of course, one can trust his facts as implicitly as though his father's name stood on the title-page instead of his own.

The book is intended as a guide for the amateur horticulturist, and, consequently, the greater portion of it consists of descriptions of plants adapted for ornamental use in the gardens and greenhouses of France. These are grouped as "Annuals," "Biennials," "Perennials," "Bulbous Plants," "Hot-house Plants" (with a special treatise on Orchids), "Trees and Shrubs," "Flowers of the South," "Flowers and Grasses to be dried for Winter Bouquets," and "Foliage and Ornamental Greens." Each division is full enough to satisfy the needs of the most enterprising amateur; the plants named in it are chosen with knowledge and taste; simple notes as regards their culture are appended, and excellent little illustrations explain their aspect. Many hints may be gathered by American horticulturists from these pages, although, of course, their indications are not always adapted to our very different climatic conditions, and he will miss certain plants which, favorites here, are less generally known in Europe.

But the most interesting part of Monsieur de Vilmorin's book for transatlantic readers is that which treats, in a general way, of the flowers of Paris—what they are at successive seasons of the year, where and how they are produced, and in what manners they are sold. It is in northern countries, as the author explains, that the trade in cut flowers and plants is regularly organized, and assumes the proportions of a national industry. In southern lands flowers grow everywhere at all seasons of the year, and, of course, are everywhere offered for sale. But the traffic in them has not been obliged to regulate itself as has such traffic in regions where frost and snow prevail during many months of the year. The greatest flower-markets, therefore, are those of Paris and London; but only in recent years has Covent Garden flower-market grown to an importance at all comparable to that of the chief Parisian market, while in Paris the trade has so largely developed of late as to necessitate the establishment of a number of smaller markets. In America, on the other hand, says the author, although flowers are used in winter as profusely as anywhere

in the world, "people have hardly the time to frequent flower-markets. They want the commodity brought to their doors. So the large towns are abundantly supplied with flower-shops, which often extend themselves largely over the sidewalks."

Monsieur de Vilmorin's description of the great market at the Halles Centrales is so interesting, and will doubtless be so new to the majority of our readers, that we reserve it for somewhat full translation at another time. Meanwhile, however, we can note his enumeration of the chief flowers sold in Parisian markets and streets at the different seasons of the year.

"In the fine days of spring," he says, "before Paris begins to empty itself, the markets are in their full splendor, . . . and purchasers are simply embarrassed to choose between flowering bulbs, early Roses, Deutzias—the favorite ornament of the month of May—the first Pinks, Chinese Primroses, Cinerarias, which have not yet gone out of bloom, innumerable Gilly-flowers, Forget-me-nots, Indian Azaleas, which are at the height of their season, Gardenias, and a hundred other varied plants. At the same time armfuls of Lilacs, Mignonette and Narcissus attract attention by their perfume, and great baskets of growing Pansies, double Daisies, Anemones and Ranunculi offer themselves for the decoration of little city gardens and window-boxes. In the middle of summer China Asters rule, with Pinks of every shade, Gladioli, now so prodigiously varied in color, Agapanthus, Gauras like white butterflies, Amaryllis of every form, Chinese Perillas with dark brown foliage, Lillies (*Lilium speciosum*) in their red and white varieties, golden Lilies of Japan with their powerful odor, Tuberoses as strongly scented, Plumbago Capensis of tender blue, Madagascar Periwinkles, and the Gypsophyla and Stevia, which give lightness to bouquets. Then, piled in baskets, are Mimulas, Verbenas, Balsams, Ageratums, Lobelias, Nemophilas and all the charming annual flowers of the open ground. The autumn is now wholly given over to Chrysanthemums. . . . Nevertheless, after them may still be seen Asters, Laurustinus, Christmas Roses, and soon Persian Cyclamen's, which begin the series of winter-blooming hot-house plants. Toward Christmas the winter-foliage decorations begin to appear—Mahonias bronzed by the cold, Hollies with their pretty red berries, the spiny Butcher's Broom, tufts of Mistletoe bearing their viscous fruits, and, coming from the south, sprays of the Japanese Spindle-tree and the American Pepper-box (*Schinus molle*) with its clusters of pink berries."

We know of no book of just this character which has been prepared in this country. But we think that one similarly moderate in size and price and popular in form, which should describe the traffic in flowers and plants that goes on in New York, the places where they are grown and the manner of their cultivation, and should give sensible lists of such plants as are best suited for amateur cultivation, might find a wide public of interested readers. At present, American amateurs have to depend upon the information contained in horticultural journals, where, of course, they may not always be able to put their finger upon such items as are most wanted at the moment; and upon trade catalogues, in which, very naturally, everything is named, everything is equally recommended, and a very undesirable degree of stress is laid upon novelties. The materials from which the American amateur may choose are even richer than those that lie ready to the hand of the European amateur; and his need of such guidance as is supplied by a book like Monsieur de Vilmorin's is greater than the European amateur's need in exactly the same proportion. To choose his materials is the first and most important step which he has to take; and, at present, it is perhaps the most difficult of all steps to take with wisdom.

Notes.

Mrs. Katherine Brandegee recently printed in *Zoe* a "Catalogue of the Flowering Plants and Ferns growing spontaneously in the city of San Francisco," which names 485 species, citing their localities. Notes of an instructive sort are added, and also a list of local Mosses, collected chiefly by Mr. H. W. Bolander.

Owing to the lateness of the season, the annual Rhododendron show of the Massachusetts Horticultural Society has been postponed until Friday and Saturday, June 10th and 11th. A special prize for fifty trusses of not less than fifty varieties, offered by Mr. Francis Brown Hayes, will be competed for at this time. On Saturday, August 6th, a silver vase valued at twenty-five dollars will be awarded for the best display of Sweet Peas. This is one of the prospective prizes of the society, and must be taken by the same person or firm twice in three consecutive years. This is the third year that the society has offered this prize.

Although as a flowering tree *Maackia Amurensis* is very inferior to its relative, the North American Yellow-wood, *Cladrastis lutea*, it is very beautiful when the young foliage is expanding, and is worth planting for the effect it produces in early spring when the young leaves have a peculiar gray-green or mouse-color, and are very unlike those of any other hardy tree or shrub. *Maackia* is now well established in many northern gardens, where it flowers profusely late in June, the minute pea-shaped yellow-green flowers being produced in slender upright spikes which make a pleasing contrast with the rich dark green foliage. The seed-pods are small and do not compare in beauty with those of the Yellow-wood.

Judged by the specimen now flowering in the Arnold Arboretum there is no shrub more beautiful at this time than *Rosa grandiflora*, with its great single white flowers as handsome as those of the Cherokee Rose and far more fragrant. This fine plant, in spite of the fact that it is an old inhabitant of gardens, is rarely seen in these days, although the growing taste for single-flowered Roses must soon bring it into general cultivation. In 1825 it was figured in the *Botanical Register* (t. 888) by Lindley, who thought it might have come from Siberia, although he was uncertain of its origin. It is of the same section as the Scotch Rose (*Rosa spinosissima*), but far excels all the varieties of that handsome plant in the size and beauty of its flowers and in the boldness of its dark green foliage.

It would be delightful, says "The Listener," in a recent number of the *Boston Transcript*, "if we could have an opportunity to see a garden laid out and kept up exactly in the Japanese manner. It would be an attractive idea to have a Japanese garden in one corner of Franklin Park. There is a sufficient number of Japanese trees and flowers which are hardy in this latitude to make it possible to furnish a garden entirely with Japanese vegetation; and the gardeners of Japan are famous for making beautiful gardens in a very little space, so that not much room would be needed. We could not have avenues of Plum or Cherry trees five miles long all at once, but we could unquestionably get some very instructive suggestions, and it would be very interesting to everybody."

Decades of North American Lichens, prepared by Clara E. Cummings, associate professor of botany at Wellesley College, and Mr. A. B. Seymour, of the Cryptogamic Herbarium of Harvard University, can be obtained by addressing Miss Cummings at Wellesley, Massachusetts. The first thirty or forty species of the series will be ready for delivery in June. These early decades will contain many of the commonest species, well suited to beginners in the study of Lichens, teachers and classes in high schools, academies and colleges. The specimens will be enclosed in envelopes or glued to small sheets ready for mounting in the herbarium, and will be accompanied by printed labels, all critical species being verified by comparison with the Tuckerman Herbarium. The price, seventy-five cents for each decade, is unusually low.

A paragraph in the *Bulletin of the Torrey Botanical Club* for May, calling attention to an article by Monsieur A. Franchet, recently published in the *Journal de Botanique*, says: "It is interesting to note the discovery in the Chinese province, Yun-nan, at an altitude of 3,200 metres, of a *Kelloggia* that closely resembles *K. galioides*, Torrey. The habitat of the latter is in the coniferous forests of the Sierra Nevada and the mountains of Arizona, Utah, Washington and Wyoming, and the finding of a second species demonstrates the extension into Asia of a genus hitherto considered solely American. *Kelloggia Chinensis* is another and interesting example of the simultaneous existence in North America and central Asia of certain very characteristic plant types. Remarkable among many such cases is that of Ram's-head Lady Slipper, the presence of which in the mountains of western China was most unexpected."

In this year's "Grand Corso and Battle of Flowers," at Florence, one of the carriages which attracted the most attention was covered—body, wheels, steps, driver's box, whip and harness—with Lilies-of-the-valley, while the ladies who sat in it were dressed in white and carried parasols of the same flowers. Another carriage, dressed also with Lilies-of-the-valley, showed on each side the family coat-of-arms wrought with red blossoms. Another was adorned with Forget-me-nots and yellow Roses, another with white Roses and pink Azaleas, another with Lilacs and white Roses, another with Forget-me-nots and very small pink Rosebuds, another with Daisies, white Lilies and Maiden Hair ferns, another all with yellow Jonquils, and still another, described as especially graceful in effect, with great masses of Wistaria. Large umbrellas formed

of flowers covered, like canopies, some of the smaller equipages, and in all cases the occupants were costumed in harmony with the decorations of their carriages.

Speaking of the extensive experiments of the Canadian Government in tree-cultivation, the *Popular Science Monthly* says: "At the Central Farm, near Ottawa, the seeds of Rocky Mountain and European conifers have been liberally sown; and in 1891 one hundred and seventy-five thousand seedlings were transplanted from the beds to be distributed later on to branch farms and private experimenters, who are to send in careful reports of progress. The Government also distributed one hundred thousand forest-tree seedlings among one thousand applicants in the northwest, with instructions for planting and subsequent treatment. Twenty-five gardens along the main line of the Canadian Pacific Railway have been supplied from the experimental farms. Speaking of the need of the application of forestry in the old provinces, Mr. J. C. Chapais mentions whole regions as known to him which were cleared by settlers who had to desert the land soon afterward because it was worth nothing. Such districts, he adds, would have been so many inexhaustible wood-reserves for future generations, but are to-day useless."

About the middle of May Secretary Lyon, of the Business Men's Moderation Society of this city, began his annual work of distributing flowers to the children of the city poor. He took his station in Paradise Park, that oddly misnamed little pleasure-ground which lies in the vicinity of Mulberry Bend and the Five Points, at three o'clock, just when the schools were dismissing their pupils. The flowers, which had been brought that morning from New Jersey, included Violets, Wistarias, Honeysuckles, Lilacs and Dogwood-blossoms, and were tied in bunches of convenient size. As they were given into the eager little hands, the scene was a noisy as well as a smiling one, and the windows of adjoining tenements were crowded with grown persons, who shared the children's delight. This special charity is not fathered by the society of which Mr. Lyon is the Secretary, but is personally his own; and most, if not all, of the flowers which he thus distributes from time to time come from his grounds at Short Hills, and are gathered and arranged by his children. More good is done in ways like this than in many of the ways with which charity has been longer familiar; and the good is to the donors, of course, as well as to the recipients. Very few New York business men can be expected to take the time and trouble needed for the actual following of Mr. Lyon's example; but there are many who, with very little trouble indeed, could regularly send quantities of flowers for distribution to him, to some hospital, or to one of the many charitable societies which would be thankful to receive and distribute them.

A developing fruit appears to be comparable with a chemical laboratory on a small scale. Here we have inorganic matter converted into organic matter, and the latter changed by the life-processes into other varieties of organic matter, in a way which we can only marvel at. Last summer ripening cherries were made the subject of a special study by W. Keim, who has recently published the details of his research in the *Zeitschrift für Analytische Chemie* (vide xxx., pp. 401-407). He specially examined the changes which take place in the chemical composition during the growth and maturity of *Prunus cerasus*. The variety studied was the early Griotte, specimens of which were gathered from a single tree, at intervals of seven to ten days, and analyzed, and the *Gardeners' Chronicle* gives a summary of the conclusions reached. As the fruit ripens the percentage of water decreases, the dry substance increases, so does the acid, and, of course, too, the total amount of sugar. In the earlier stage of maturity, citric acid (the acid of lemons), malic acid (the acid of apples) and succinic acid are present, but nine days before perfect maturity is reached the latter quite disappears. Invert sugar is present from the start, and in the last stage is ten per cent. of the entire weight. Dextrose and levulose (two sugars) are present, with inosite, another sweet substance at first, but toward the end the inosite occurs merely as a trace. The progressive increase in the percentage of acid during the whole period is not in harmony with the old view that the sugar is formed at the expense of the acid. The disappearance of succinic acid as ripening is approached suggests the theory that the other acids are formed synthetically. Cane-sugar is present only in the leaves, in proportions which increase as the ripening is approached, but subsequently diminishes. No starch was detected at any stage in the growth of the fruit, though the parenchyma-cells of the peduncle showed starch-granules, increasing in amount as the fruit ripened.

American Poplars.

THE genus *Populus* is not a large one, although the species are widely scattered, and no other trees, perhaps, play a more important part in the economy of nature. Poplars are not easy to understand, although, like the Willows, to which they are closely related, the structure of the flowers is very simple. The two sexes, however, are separated on different plants, and individuals show a perplexing tendency to vary in habit and in the form of the leaves, while natural hybridization increases the difficulties of the student, who finds among them, too, uncertain varieties of unknown origin long known in cultivation.

Poplars grow in the boreal parts, on the mountain-ranges, and by the banks of midcontinental streams in both northern hemispheres, and often attain a large size in places where no other tree can exist. They are able to support intense cold and great atmospheric dryness if their roots can reach water; their light seeds are produced in immense quantities, and, furnished with an appendage of buoyant hairs, are blown far and wide in spring and early summer, and reaching the ground, while it is still moist, germinate quickly, while broken branches carried by wind or water often root when they reach the ground. Poplars, therefore, are unusually well equipped with means for multiplication, and are able to spread over large areas where less favored trees cannot obtain a foothold.

In North America eight species at least may be distinguished; the most valuable of them, although the smallest, is the so-called Quaking Aspen (*Populus tremuloides*), a tree very similar to the Old World Aspen (*Populus tremula*). The value of this little short-lived tree, which rarely attains the height of fifty feet, is not in the wood it produces, for this is small and of no value except in paper-

making, but lies in the power of its seed to germinate in burnt soil and in the rapidity with which the young seedlings grow and cover exposed surfaces of bare ground. By holding the soil on mountain-slopes and affording shelter for the seedlings of longer-lived and more valuable trees the Aspen has played a conspicuous part in the perpetuation of forests, and no other plant, perhaps, from the time it appeared in direct descent from a familiar type of the tertiary Arctic flora to the present day has had so great an influence in the composition and distribution of the subalpine and boreal forests of North America. In its present form the American Aspen ranges from Newfoundland to Labrador and Alaska, and southward through the northern states, and over mountain-ranges of the interior of the continent, where it ascends almost to the upper limits of tree-growth, marking steep and barren slopes with broad light-green splashes, which in autumn glow like gold against the dark background of rocks and stunted Pines.

A tree of larger size and of circumpolar distribution, for it is common in Europe and Asia as well as in America, is *Populus balsamifera*, commonly called in this country Balsam and Balm of Gilead, because the buds are covered with a resinous balsamic exudation which is sometimes used medicinally by rural practitioners. In America this fine tree ranges from the shores of the Straits of Belle Isle to Alaska, and southward to within the northern borders of the United States. It is very common in British America, where on low sandy river-plains and islands it constitutes forests of considerable extent and plays an important part in controlling and directing the drainage of a vast territory. In cultivation the Balsam is a handsome tree, especially the variety *Candicans*, of uncertain origin, which is distinguished by its large leaves, pale or nearly white on the lower surface; it is very hardy, it grows with surprising rapidity, and in cold countries no tree will attain to a large size in so short a time. Like other Poplars, however, the branches are brittle and easily broken, and the trunk is often injured by boring insects which prey upon all the trees of this genus, especially when they are isolated in cultivation or planted in too warm a climate or in too dry soil.

Closely related to the northern Balsam is a tree of western America, where it ranges from British Columbia to southern California. This is the *Populus trichocarpa* of recent authors, who find in its pubescent ovaries and fruit sufficient reason of its specific distinctness. The western Balsam is one of the tallest of the genus, and individuals approaching two hundred feet in height, with tall, slender stems, are not rare at the north, where it forms handsome open groves by river-banks at low elevations, while at the south it seeks a cool and humid atmosphere by climbing into mountain cañons, which it decorates between four thousand and six thousand feet above the sea-level. In the picture on page 281 of this issue, taken from a photograph made by Dr. William H. Rollins, appears a well-known grove of the western Balsam on the banks of the Merced River in the Yosemite Valley, from which our readers can gain a good idea of the general appearance and manner of growth of this tree in central and northern California, where it does not attain such a large size as it often does in Oregon and Washington.

The familiar Cottonwoods which line the banks of the great rivers and of the scanty and uncertain streams of the central and south-western parts of the country are Poplars, whose bright green foliage and grateful shade have cheered the hearts and excited the imaginations of thousands of worn and discouraged travelers on the plains and deserts of western America. To three trees, the name of Cottonwood due to the white silky hairs attached to the seeds, has been indiscriminately given. The first of these is the Carolina Poplar (*Populus monilifera*), an inhabitant of river-banks in all the country from eastern New England and northern Florida to the eastern base of the Rocky Mountains; it is the common Cottonwood of the streams

which flow eastward from the Rocky Mountains, and under favorable conditions grows to the height of one hundred and fifty feet, and sometimes forms trunks eight or nine feet in diameter. It is a beautiful tree with a tall straight massive trunk, a spreading head and large lustrous leaves, and of all Poplars is perhaps the most desirable as an ornamental plant. The wood, like that of all the species, is light and soft, but close-grained; it is, however, very difficult to season, and is apt to warp badly in drying. Of late years it has been somewhat used in the Mississippi valley, where the Carolina Poplar is abundant, for cheap packing-cases and other coarse work, and it is now probable that this tree is to play an important part in supplying the country with certain low grades of lumber.

The second species of Cottonwood is confined to the banks of the streams of the Rocky Mountain region, where it is found from the Black Hills of Dakota to Colorado, New Mexico, Nevada and Arizona. It is a small tree, usually under sixty feet in height, and is distinguished by its narrow entire leaves to which it owes its name, *Populus angustifolia*.

West of the Sierras of California, from the valley of the Sacramento southward, the third species, *Populus Fremontii*, is found—a large tree not to be distinguished from the eastern *Populus monilifera* except by the structure of its flowers and fruit, and, to untrained eyes, apparently identical with it in habit, foliage and beauty. In the southern part of California this tree is replaced by a well-marked variety, still too imperfectly known, which is common on the borders of all streams in that part of the state and in Arizona, southern New Mexico, western Texas and northern Mexico, where it is the ordinary shade-tree of city streets (see GARDEN AND FOREST, vol. i., p. 104). Economically this last is a tree of great value as it furnishes the fuel of the people living in the territory adjacent to our southwestern boundary, where it is planted near streams and irrigating ditches, and every few years the large branches are lopped off and supply all the fuel needed for cooking.

In the forests of eastern America two other Poplars are found, *Populus grandidentata*, so called from the cutting of the leaves, a handsome small tree of the north, and *Populus heterophylla*, the River Poplar, a tree of no great size, which inhabits deep, wet swamps in the eastern and southern states, and the rarest of all our species, although it can be found in two or three localities in the neighborhood of this city, notably at Northport, on Long Island, and on Staten Island, where a few years ago Professor Britton made known its existence in considerable numbers.

The General Design of the Columbian Fair Grounds.

THE committees of the Chicago Commission, upon whom has devolved the responsibility of selecting the site and constructing the buildings for the Columbian World's Fair, have proved that they appreciate the true function of the landscape-gardener in works of that character where gardening in its accepted sense plays a very subordinate part. They did not make choice of a site, select places for the various buildings, and then invite the advice of artists in landscape to devise some scheme of planting for decorative effect. The first experts consulted were Messrs. Olmsted & Co. It was realized at the outset that the entire work was to be treated as a unit; that there was to be a general design which should solve, in the most satisfactory way, all the problems which might confront the organizers of so vast an undertaking, so that the amplest facilities should be offered to exhibitors and visitors, and that these should be combined with the noblest artistic effect.

It is no discredit to the architects who are doing such splendid work in Chicago to say that in one sense their individual efforts are subordinate to the general scheme—that is, each building is really a detail of the design which includes them all. Of course, it was necessary for the Messrs. Olmsted to consult with Mr. Burnham, Chief of Con-

struction, and Mr. Root, the Consulting Architect, as well as with the designers of the separate buildings, but, after all, it was the primary and peculiar office of the landscape-architects to discover all the possibilities of the site and prepare the foundation and frame-work of the general arrangement; to estimate to some extent the proper size of each building, and to place it in the best position, both for convenience and beauty; to study the grouping of them all not only with regard to their practical relations to each other, but also with regard to the impressiveness of their appearance in combination. In this case, as in many others where the counsel of men who stand in the foremost rank of their profession is secured, apparent difficulty was transformed into opportunity. The necessity of elevating the swampy ground into terraced levels above the water-line to make foundations for the massive structures left excavations, which were turned into canals and waterways. These not only increase the facilities for conveying visitors from one part of the ground to another by making it possible to land them at any one of the buildings, but they heighten in a marked degree the beauty of the scene. Verdurous shore-lines and bright stretches of water are thus made possible, and the prevailing stony effect of the buildings is relieved from many points of view by masses of foliage on the island which has been raised above the lagoon, while the buildings themselves are never as imposing as they are when seen from the boats which float below the line of their bases.

All this emphasizes the fact that the landscape-gardener is not, as he is too often considered, a sort of mere outdoor decorator and furnisher. His work is serious, practical and serviceable in the highest sense. Even in public parks and pleasure-grounds, where architecture plays a less important part than it does in the case we are considering, it is too often forgotten that a good design involves the settlement of numberless questions of every-day practical availability apart from the development of its landscape beauty. Of course, it is not meant by this that landscape beauty is sacrificed to what is commonly considered utility, for in such a case the beauty itself gives to the park its highest usefulness. The problem is to preserve and create beauty where it is possible, and at the same time to provide for great numbers of people in movement and at rest, to secure their distribution so as to prevent overcrowding at special points, to supply the conveniences and comforts and amusements demanded by different ages, sexes, conditions and tastes. Architects who design dwelling-houses for private places are learning that they can be materially aided by expert counsel in determining for such buildings the proper site, approaches, aspect, outlook and other points in which they are related to their surroundings. Such counsel is quite as useful to the health and convenience of their clients as it is to the beauty of the home picture. This means that true landscape-art, like the best architecture, is the "decoration of a service." Its real value is based on the fact that it adorns what is useful.

The Chicago Commission deserves the thanks of the country, not only because it has secured for the great exhibition the services of eminent architects, who are working together in perfect sympathy, but because this harmonious labor was made possible by trusting to experts to furnish a general design toward which they could all work with unity of purpose. Besides this, an example so striking as this ought to exert a wholesome influence in helping to establish landscape-gardening in this country in its proper position among the arts of design.

THE Botanical Club of Washington, District of Columbia, at a recent meeting, unanimously adopted the following report of the Committee on a Botanical Congress and Nomenclature:

"Resolved, That, while favoring the final settlement of disputed questions by means of an international congress,

we do not regard the present an opportune time, but that we recommend the reference of the question of plant-nomenclature first to a representative body of American botanists.

"We suggest the consideration, by such a body, of the following questions among others: The law of priority; An initial date for genera; An initial date for species; The principle, 'once a synonym always a synonym'; What constitutes publication; The form of ordinal and tribal names; The method of citing authorities; Capitalization? We recognize the Botanical Club of the A. A. A. S. as a representative body of American botanists, and commend to that body for discussion and disposal the subject of nomenclature as set forth in these resolutions."

These subjects are important to every botanist. It is to be hoped that the projected movement will be responded to and that it will receive the support of all persons interested, so that these questions shall no longer vex American botanists.

The Flower-trade of Paris.*

FLOWERS and always flowers, in the dog-days as during the hard frosts of winter—this is what the Parisian public demands. As long as a low temperature does not interfere with the growth and expansion of flowers in our latitude, the horticulturists of the environs of Paris almost altogether supply its markets. But as soon as cold weather arrives, the artificial heat of the greenhouse must replace solar heat; and if this alone were available, horticultural products would be very costly. Happily, therefore, now that rapid transportation has developed so marvelously, a part of the necessary floral provision of Paris comes from the south of France—from the shores of the Mediterranean.

Whether they come from the immediate neighborhood or from the most distant provinces the flowers all converge, in arriving at the capital, toward a central point, whence they pursue their journey in various directions according to their purchasers. This centre of the trade is at the Halles Centrales, or main market of Paris.

Every night, at Paris, shelters with its darkness a spectacle well worthy of being displayed by day. Strangers seldom witness it; but this greatest flower-market in the world must be seen if one would understand the importance of the trade in flowers and the number of persons whom it occupies. At present it is inadequately accommodated; but it is proposed to build in the Halles a special structure for the flower-trade, or else to create for it a wholly independent market-place.

The flower-market is now held, in a tremendous draught, beneath the shelter of a covered street which crosses the great market. In this cold passage-way, open to all the winds of winter, flowers begin to arrive as soon as night falls. First, heavy railroad trucks bring the consignments of the south in very light boxes and baskets of willow or of split and braided reeds. Then come the growers of the vicinity of Paris, bringing their wares in two-wheeled covered carts, and having started at different hours, according to the distance they had to traverse. All try to arrive as early as possible in order to secure a good station, or else send representatives to secure one, arriving themselves at a later hour, shortly before the opening of the sale.

Discharged from the trucks and wagons, the merchandise is spread upon the sidewalks and a portion of the asphalt road. Each seller pays, per diem, four or five cents for each metre of space, according as it is sheltered or exposed. Some thirty of them, however, pay for their stations by the month. Paths are left between the masses of flowers of different exhibitors for the free circulation of purchasers.

As the temperature falls during the long dark winter nights, the waiting is tedious and the wind is very chill. Protected by thick coverings and guarded with solicitude against anything that might diminish their commercial value, the flowers themselves are less to be pitied than their unfortunate proprietors. But when the weather is very inclement the sale is transferred to the vast cellars under the Halles, and the aspect of the flower-market is then very picturesque. Temporary and shifting stations are established, tables are made with wooden horses, and on these tables are displayed the flowers which, in these days of heavy frosts, are of few varieties—Violets, yellow Narcissus, with Roses and Mimosas from Cannes.

The sale commences at three o'clock in the morning in summer, and at four in winter. Then the animation and activity of the market are remarkable. At this hour there are few amateurs. All transactions pass between tradespeople, who, as a rule, know one another, and are rapidly accomplished. Most of the purchasers are middlemen, who later sell again in the city what they have bought in the early morning. And we also see traders who, without leaving the market, embark in quick and apparently remunerative speculations. At the beginning of the sale, while the flowers are abundant, they buy them for low prices, and then, hiring a seller's station, they wait till values have gone up, and, displaying their wares with taste, dispose of them at a profit. Dealers of this sort are called hucksters.

Every one is not free to cry his wares in the market. Only two individuals have this right, and for it they make a deposit of 10,000 francs. Moreover, the entire market is under police surveillance, and everything proceeds in an orderly way.

The *Commissionnaires de Fleurs* (flower agents) and the *forts* (porters, or, literally, "strong men") still remain to be mentioned. The *Commissionnaires* are forty in number, and perform a double function. In the first place, they facilitate the use of the market for producers living at a distance. Every Provençal horticulturist cannot afford to keep in Paris a representative to receive his consignments, carry them to the market and superintend their sale. So he arranges with a *Commissionnaire*, who takes charge of the reception and sale of the flowers, reserving, of course, a percentage of the receipts for himself; and meanwhile, from this centre of the trade, he keeps his client informed of all its fluctuations, so that he may direct his efforts to the best advantage. In the second place, the *Commissionnaire* performs a very useful work of selection. From the enormous quantities of flowers which he receives, before they are taken to the market he separates the rare and much-sought-after ones, and sells them to the chief florists and to rich amateurs. The whole cost of the production and transportation of a consignment may thus sometimes be paid for by a few choice articles, which are called the "Very Fine South" (*le très beau midi*), so that the remainder, which is called "Ordinary South" (*le midi ordinaire*), when taken to the market can be sold so cheaply that afterward, from the barrows of the peripatetic peddler, we can buy them more cheaply in the streets of Paris than at Nice or Cannes. On an average these *Commissionnaires* receive, altogether, some thousand or twelve hundred baskets of flowers, which come chiefly, especially in winter, from the south; the number of the local florists who come in person to the market varies during the different seasons, being greatest in summer, but on an average they deposit about 800 baskets of flowers at their stations, and so some 2,000 basketfuls are sold daily at the Halles.

The *forts* of the Halles are famous, and form an ancient corporation, the honesty of which is proverbial. They unload each wagon as it arrives, and give its proprietor his station-ticket, so he can go in peace to put his wagon in an indicated spot on one of the neighboring streets, while his merchandise is being carried to his station by the *forts*, who are responsible for its safety. And for ten cents a night his wagon and horses are cared for by another band of employees specially charged with this duty.

At nine o'clock the sales are finished. The peddlers' wagons, with their loads complete, scatter through the streets; the florists send their purchases home in hand-carts; and the growers take the road again, sleeping the sleep of the just under the great green hoods of their wagons, while their horses follow their own wills, encumber the middle of the high-road, and sadly impede circulation.

The Time of Roses.

THE path which rises at the back porch and runs, in an easterly direction, between banks of Peas, Beans and Strawberries throughout the length of the vegetable-garden until it is finally lost in a sea of wavy Wheat, is bordered on both sides throughout its course by a number of old-fashioned shrubs and other plants. Among these is a Rose which wanders at will over the grassy banks and is just now in perfection of bloom, glorifying the vegetables and even lending a touch of poetry and grace to our Tomatoes and Cauliflowers. This is a Damask Rose planted fifty years ago by the dear old lady who, with her white-haired husband, once lived at Rose Brake, and was as enthusiastic over the flowers of her day as are we over our newer loves. To this old lady we are indebted for the blue and white Irises which cluster at the foot of the large old Cherry-tree, a sapling in her time, for the exquisite double

* Translated from Monsieur Philippe de Vilmorin's *Les Fleurs à Paris*.

white Narcissus, as handsome as a Gardenia, and the many Daffodils and early Jonquils which have formed numerous thriving colonies in the grass; for the Cinnamon, Hundred-leaved and other old-fashioned Roses; the stately Yuccas and many other charming plants. Among these the old Damask Rose, with exquisitely sweet, semi-double, large, flat flowers of a rich bright carmine, is a prime favorite. One variety is striped with white, and is the York and Lancaster Rose, now seldom seen except in old gardens or pressed between the leaves of venerable volumes of poetry by hands that have long been still.

In the Rose-garden, at one side of the house, very many aspirants for the prize of beauty have now entered the lists, and it would puzzle the most critical connoisseur to decide where to bestow his warmest praise. Madame Alfred Carrière has reached the stately height of sixteen feet, and is bending under a weight of flowers; there are hundreds of these large double roses scenting the warm June morning. No doubt, the mother cat-bird, whose secret is deftly hidden in the midst of a perfumed cluster, thinks that all this display of grace and beauty is in honor of her downy nestlings, in whose praise the father bird sings all the day. Turning from this pretty picture the eyes are greeted on all sides by a profusion of Roses, old and new, scrambling over rocks and palings, climbing up the little arbor, which they share with many Honeysuckles, or confining their fresh luxuriance to more orderly beds and borders, where they mingle many tints and varying odors into a perfect harmony of joy.

There is the fairy bed of tiny Polyanthas, which are always to be depended on for an abundance of rosette-like blossoms; the white Paquerette, smallest of Roses, just the size of a five-cent piece; the charming pink Georges Pernet; the beautiful salmon-colored Perle d'Or, a miniature likeness of Safrano, and the blush and cream of Mademoiselle Cecile Brunner, larger than the rest. All these are faintly sweet except Paquerette, which has a strong and unpleasant odor—strange in a Rose, and stranger still in a Fairy. Another drawback in Paquerette is an ambition leading it to begin much more than it can accomplish. Never were seen so many little buds, most of which turn yellow in infancy and come to an untimely end. Only two of the best colors are missing from this little bed. We have as yet no bright or dark red Polyantha, and none of a lemon-yellow. These may exist, and would be a pleasant addition.

On the south side of the house grow some climbing Polyantha Roses. One of these, planted two years ago, has reached the windows of the second story, but has not bloomed. Another, Max Singer, is showing a number of blossoms, and is very double and slightly fragrant. It is a light pink in color, not a very pretty shade, but the plant is vigorous and hardy. Very few yellow Roses do well with us out-of-doors. Harrison's Yellow is pretty at this time, but the finer Teas are too delicate to be of much use in our garden, where plants which can take care of themselves best, and live and flourish with the least coaxing and coddling, are the favorites.

Sunset, Perle des Jardins, Madame Welche, and very many other golden beauties, have all been tried with varying want of success. Beautiful Madame Joseph Schwartz lived and bloomed for several years, and then died of rapid consumption just as we had reason to hope that its health was established. Perle des Jardins is a great bush, but the heavy buds do not open well; indeed, they do not open at all, but blight and turn brown upon the tree. Isabella Sprunt consoles us for many failures. The bush is five feet in height and about the same in circumference, and gives us dozens of perfect, not very double, lemon-yellow Roses, best in the half-opened state. Safrano is also very satisfactory, never failing us, and so are Laurette, which is cream-colored, and is not a Tea, but probably a Noisette, and Madame Hippolyte Jamain, a very lovely Tea of delicate habit and flowers which are outwardly white, with a fine salmon heart. These Roses have stood the test of many winters, and seem to improve with age.

The old-fashioned Hundred-leaved Rose, and some hybrids of Provence whose names I do not know, are the best for pot-pourri, for rose-water and for filling dainty sofa-cushions. These are now beginning their annual struggle with the slug, which has not appeared in as great numbers as usual, the cold spring having apparently checked their increase.

Among the rarities now flowering in the shrubberies is a variety of *R. rugosa*, which is labeled *R. rugosa*, var. *Himalaya*. This is a large bush, with smaller, lighter, less glossy foliage than that of the common variety. The flowers are double, but in other respects they do not differ greatly from the type.

Thompson's Magnolia is fading in the White Garden. This is a beautiful Magnolia; the flowers are at first large creamy

cups, falling flatly open before they fade. It is a hybrid of *M. glauca*, I believe, and blooms when only four feet in height.

Cornus paniculata and *Robinia viscosa* have been conspicuous in the shrubberies for the past week. The Pæonies are making a gorgeous display in their isolated bed, where the grass of the lawn forms a fine setting for them. Vicomtesse de Belleval and Modeste are the handsomest now in flower, with an almost pure white variety, very double and sweet-scented.

Danske Dandridge.

New or Little-known Plants.

A New Water-lily.

NYMPHÆA LAYDEKERI ROSEA is a new hybrid Lily introduced this year by Monsieur Marliac, who has previously added *N. chromatella* and numerous less well-known Nymphæas to our collections. This variety having only been sent out in the late spring, the plants have not had time to become thoroughly established and show their best form. But as they are now in flower quite as early as established plants, it may be well to note the variety as it now appears. The flowers are rosy pink of a deep tint, deepening toward the base of petals. They are single, and in form very much resemble those of *N. pygmæa alba*. The deep orange stamens also resemble that variety in their arrangement. The leaves are small, broadly sagittate, smooth, very slightly undulated, a vivid green above and of a reddish hue under. The flowers at present open are about twice the size of those of *N. pygmæa alba*, and open about ten o'clock A. M., closing in the late afternoon. It is evidently a thrifty, quick-growing variety, and, as it is said to flower continuously till October, it will prove a welcome addition to our collections, though probably not a variety of first rank in size of flower.

Foreign Correspondence.

A Visit to Mount Salvatore in May, 1892.

IF there is anywhere a mountain made to charm the heart of a lover of plants it is the proud pyramid of dolomite which rises to the south of Lugano, its base completely surrounded by the arms of that lake, the most beautiful sheet of water of the Italian slopes of the Alps, known as Ceresio, or the Lake of Lugano. This pyramid is Mount Salvatore, now accessible to all the world by means of a little cable-road boldly pushed up its steep flanks. It is not a high mountain, for its summit is less than four thousand feet above the level of the ocean, but the boldness of its outline and its steep slopes and vertical cliffs give it a truly imposing aspect, and its flora, especially its spring flora, contains a number of plants rarely seen outside of gardens, which are here luxuriating in their native wilds. The base of the mountain is wooded with venerable Chestnuts; over the slopes are spread thickets of many species of shrubs, while the summit is covered with a delightful sub-alpine vegetation. Here may be seen *Daphne Cneorum*, which looks like a diminutive alpine *Rhododendron*, the flowers delightfully fragrant, like those of all the family; *Erica carnea*, a lovely Heath with bright rich red flowers, and *Polygala Chamæbuxus* in its two varieties, the one with white flowers, a common plant in the Swiss Alps, and the other with red flowers, a variety only known on this mountain. The flowers with their bright purple wing-petals and golden keel are probably the most beautiful of the genus, their charm being heightened by the evergreen leaves and the compact habit of a real alpine plant. I cultivate this beautiful variety in my garden, and I can recommend it for rock-work.

Among other shrubs is *Cytisus Laburnum*, which, on every side, hangs out its long clusters of bright yellow flowers, a real shower of gold, *Ostrya carpinifolia* with its Hop-like blooms, *Cytisus hirsutus* with large sulphur-colored flowers, *Rhuscus aculeatus* with bright coral-red berries appearing on the middle of the branches dilated into leaves, and *Amelanchier* with its long pure white petals. But the most interesting plants of the mountains are those which grow under and among the bushes. The entire wood is filled with the dark green leaves of innumerable plants of *Helleborus niger*, the Christmas Rose, so dear to us all and the familiar ornament of our peasant-gar-

Fig. 52.—A Group of *Populus trichocarpa* in the Yosemite Valley.—See page 277.

dens, in which the white flowers tinged with rose generally appear at Christmas-time. The abundance of this beautiful plant in the woods of Salvatore is prodigious, and the effect produced by its flowers, which last from November until February, must be delightful. But this is not all, for with *Anemone Hepatica* appears *Cyclamen Europeanum*, which, by thousands, spreads its handsome circular leaves, dark green spotted with white on the upper and vinous red on the lower surface, and in summer enlivens the shades of the forest with its delicately fragrant red flowers. The rosettes of foliage of *Anemone Hepatica* vie in grace with the *Cyclamen*, and in one spot I noticed the white variety of *Vinca minor*, which is an exceedingly rare plant outside of gardens. On the margins of cultivated meadows and terraces appears *Narcissus radiflorus* with a white perianth, the cup bordered with red; the brilliant flowers give the fields the aspect of a garden. There are, besides, clusters of *Galanthus nivalis* and of *Primula acaulis*, with its dark yellow flowers, clumps of the robust *Helleborus viridis* with green flowers, and of the beautiful *Myosotis sylvatica* of tenderest blue, the bright purple flowers of *Orobis vernus*, var. *tenuifolius*, of *Symphytum tuberosum* with its yellow pendent bells, and here and there the noble *Struthiopteris Germanica*, with the curious *Dentaria bulbifera* with its living bulblets in the axil of each leaf and peduncle, as well as its congener, *D. pinnata*, with its great white flowers. These add interest and variety to the upper slopes, and in summer the flanks of Salvatore facing the east, shelter flowering masses of the most beautiful of the *Scabiosas* (*S. graminifolia*) with its silvery linear leaves, and the white-flowered *Helianthemum polifolium*.

The walls of dry stones, which abound in this country, deserve special attention, for, thanks to the humidity of the climate, they are covered with a thick carpet of verdure composed of rare and beautiful plants. The thick sod of *Asplenium trichomanes* forms the principal part of this covering, in which appears the delicate *Selaginella Helvetica*, whose last year's fronds are distinguished by their bright red color; *Ledum album*, var. *maximum* and var. *cetæa*, the Maiden Hair Fern, *Adiantum Capillus-Veneris* and *Asplenium Adiantum-nigrum* are mingled with *Ceterach officinarum*, covered with its dark brown scales. On the blocks of granite found among the limestone of Salvatore, *Asplenium septentrionale*, *Mœhringia trinervia* and *Cardamine impatiens* grow side by side with splendid clusters of *Cystopteris fragilis*. These plants form the principal vegetation of the walls which line the paths of the base of the mountain. Those walls, so beautifully decorated by nature, suggest the possibility of imitating her example and of clothing our own dry walls with the plants which affect naturally such situations, by transplanting them into the cracks between the stones. In doing this the gardener will be able to convert his bare and ugly walls into a charming flower-garden, where he will find that many rock-plants, which cannot be cultivated in any other way, can be made to flourish. It is only necessary to inspect the garden of the late Monsieur Boissier, the distinguished botanist at Valleyres, in Switzerland, to understand how many rare plants, which he found impossible to grow in any other way, can, when planted on walls, be made to thrive as luxuriantly as if they had been planted by nature.

I can only give a brief account of the floral treasures of Salvatore; it certainly does not contain a more beautiful plant than *Helleborus niger*, which possesses the marvelous faculty of developing its charming flowers in the middle of winter, surrounded by snow, in a very low temperature—a flower which is the touching emblem of the joy which the Christmas-time brings to us all.

Bâle, Switzerland.

Notes on Shrubs.

SPIRÆA THUNBERGII is the first of the *Spiræas* to develop flowers in this latitude. The present season was a little more backward than the average, and the first blossoms became conspicuous in the latter days of April. The fruit of this pretty species is now well advanced toward maturity. It ripens here about the first week in June, and any one desirous of raising plants from seed should carefully observe when the little capsules begin to open and collect them before the seed escapes. The seed germinates very readily, with shade and moisture and the slightest covering of soil, and will start at once and make good little plants by the autumn of the same season in which it ripens. In two or three years such plants will be bearing flowers. Of course, a more expeditious way

of obtaining new plants of this species is by cuttings, and strong young plants may be very easily propagated by green cuttings, taken at this season or a little later, and started in a moist atmosphere, as under a bell-glass or glass frame. *S. Thunbergii* is one of the most useful of all shrubs for planting in shrubberies, because, besides its ornamental flowers, its delicate foliage is interesting and beautiful all summer long, and in the autumn its colors are hardly surpassed by those of any other shrub in cultivation, and the leaves have the merit of persisting for an unusually long time.

For a double-flowering *Spiræa* the old-fashioned plant called *S. prunifolia* is the only really hardy species as yet available for our northern gardens, and the foliage of this is also notable for its bright autumn coloring. The flowers this season have been less beautiful and satisfactory than usual, owing to wet weather and long-continued cold. We have not yet had a plant with single flowers which could certainly be called the wild type of this double-flowering favorite in gardens.

All persons interested in the double-flowering forms and who have space and patience for experiments should try the double form of *S. Cantoniensis*, which is, perhaps, more commonly known among nurserymen as *S. Reevesiana*. The flowers of this are the largest and most beautiful of any in cultivation, but in this latitude the fault of the plant is that it is not perfectly hardy. Some years it survives the winters better than others, but we always expect the tips, and often portion of the older wood, to be killed, even with a good deal of protection. The blossom of the single-flowered form is much handsomer than that of *S. trilobata*, of which the supposed form, or hybrid, known in the trade as *S. Van Houttei*, is the best of all the thoroughly hardy *Spiræas* for cultivation at the north. This *Spiræa* and *S. Cantoniensis* blossom at the same time, and are just now (June 3d) in their best and most beautiful condition. There are various species and forms of *Spiræa* which are intermediate in their time of flowering between the earliest blooming and these, but most of them are characterized by blossoms with a yellowish or greenish tinge instead of being pure white, and they are, therefore, not so attractive as the flowers of Van Houtte's *Spiræa*, which are large and quite white, and are set off by peculiarly clean-looking dark green foliage. In good soil the plant grows four or five or more feet high, becoming widespreading by the bending and arching over of its stems and branchlets, whose upper sides are covered by numerous umbel-like corymbs of flowers.

Any person able to afford space for but one *Spiræa*, and wishing that one for its blossoms, should select *S. Van Houttei*, if the climate is as severe as that of Boston. The blossoms of many of the white-flowering species of *Spiræa* possess a peculiar odor, not agreeable to most people. This odor is less noticeable in the flowers of *S. trilobata* and of *S. Van Houttei*, and is almost entirely absent in *S. Cantoniensis*, so that the value of its large handsome flowers is thus enhanced.

The flowers of shrubs are most abundant at this season. All of the early *Spiræas* have white flowers, and the closely allied Pearl-bush (*Exochorda grandiflora*) surpasses them all in the snowy whiteness of its bloom. It is sometimes complained that the flowers lack individual interest, are cold and without anything to excite sentiment or admiration except by the almost dazzling effect of the full bloom. But, although the blossoms are formal and almost bold in effect and lack agreeable fragrance, they appear after Apple-blossoms have faded and before *Deutzia* and *Philadelphus* flower, and certainly at this season we have nothing surpassing it in effectiveness. The flowers themselves are most interesting just as the buds are opening. The great fault of the plant is its open habit and thin uninteresting foliage. Except when in bloom it has no value, and it needs to be massed with other shrubs that its defects at other seasons of the year may be hidden. It is not considered an easy plant to propagate, and probably the amateur will procure new plants most readily by layering at this season. Few seeds are produced on young plants, but as they get old they often fruit quite abundantly, and as the seed grows quickly new stock may in this way be easily procured.

Close beside the Pearl-bush, in botanical order, is placed the old-fashioned *Corchorus* of our gardens, a name which should be supplanted by that of *Kerria Japonica*, as being more correct and quite as euphonious. The most common form seen is the double-flowering one, which some amateurs have been known to call a "Flowering Almond with yellow flowers." But the double-flowering form is not nearly so charming and beautiful as the single or aboriginal form, whose five bright golden petals and numerous long stamens in each blossom give it something of the appearance of a *St. John's-wort*. The flowers average nearly an inch and a half across, and as they are produced singly on slender stalks, and are set off by pretty

light green foliage, they have a peculiarly attractive effect when a plant is in full bloom. A situation where it can have partial shade is the best for this shrub, as the flowers become bleached sooner in intense sunlight.

The plant is not what we would call thoroughly hardy in all situations in this climate, as very frequently many of the branches or tips of the branches are destroyed during winter. But once well established it will generally thrive in a partially sheltered and well-drained situation. It may be propagated by cuttings, layers or by division of the roots, and pieces of roots will also put forth sprouts and make good plants. The stems of *Kerria* are of a light yellowish green color, with something of the effect produced by some Willows or Cornels, so that in winter they form a striking contrast among the stems of other plants in the shrubbery. There is a form of this with white variegated leaves, but it should not be selected except as a monstrosity or curiosity.

Arnold Arboretum.

J. G. Jack.

Hardy Narcissi.—II.

EVERY year these interesting spring bulbs are more widely grown, the dealers tell us, and frequent inquiries are made for the choice hybrid varieties included in the Leedsii, Barrii and Burbridgei sections. These varieties differ but little from each other, and if many of each section are grown labels are necessary for their identification to any but the most expert. Among the Burbridgei varieties Falstaff is the most striking. The perianth segments meet and form a perfect flower without any of the starry look, which is a feature in many varieties. Constance is another good kind, and John Bain, Guinever and Edith Bell are cheap and good. The principal feature of this section is their pure white perianth and general likeness to the Poet's *Narcissus*, although most of them flower earlier than that species. The centre of the flower is cup-shaped, often distinctly margined with orange or scarlet, although these markings are hardly as distinct as the catalogues would have us believe. The climate, soil and season may, however, be responsible for variations.

The Leedsii, or Eucharis-flowered kinds, contain many beautiful varieties; these are high-priced, and are, therefore, not generally cultivated, but one of them, *Duchesse de Brabant*, should be grown in any collection, however small. It is a free and early flowering kind, coming in with the varieties of *N. incomparabilis*. It is always noticeable for its chaste elegance and for the number of flowers of somewhat starry outline. While the Leedsii kinds are said to have white perianths, it is not the white of a *Poeticus*, but is of a creamy shade. *Duchesse de Brabant* would be a good variety for pot-culture, owing to its early flowering, and it is easily obtainable in quantity at a low price. Barr's hybrid or chalice-cupped *Daffodils* may be said to resemble the varieties of *N. poeticus* in shape, but the perianth segments are of various shades of yellow, with the cup distinctly edged with orange. Of these, *Conspicuous* is a variety of marked beauty. The flowers stand out on long stems, and are remarkable for their durability. In the four varieties we have tried there is not one that could be spared. *Orphée*, *Maurice Vilmorin* and *Sensation* are good and distinct from each other. The varieties of *N. incomparabilis* need, perhaps, no description except the division that contains the well-known *Sir Watkin*, in which are classed many that are free growers and useful for cutting, such as *Stella*, which is also a good kind to force, and *Cynosure*, a bold variety, with very long stems and striking flowers. These varieties are robust growers and need plenty of encouragement, with perhaps a biennial transplanting in August, or exactly similar treatment to the *Bicolor* and *Trumpet* major kinds. *William Wilkes* is a valuable late-flowering kind, though not sufficiently established yet to bear out the character given it. *Hume's Giant* is one of the straight-crowned *Daffodils*. It is distinct from most other kinds, but the stems are short and the flowers drooping, so that it cannot be seen to advantage unless it is planted on a level with the eye, as on a rock-garden. The same is true of *N. capax plenus* as to habit; the flowers of this variety are double and consist of six rows of petals placed one above the other in the form of a star. This variety is interesting in a collection, but must be planted among the weaker-growing kinds. It has no affinity to the *Poeticus* group, the color being pale primrose-yellow. I find that very few cultivators care for double *Daffodils* and call them monstrosities, which is technically correct; but who can find it in his heart to say that wild double *Daffodils* running riot in the fields are monstrous? I have seen acres of them, and have gathered them in pasture-fields by the armful at Easter-time. The owners would willingly have paid any one

to dig out the bulbs, for cattle will not touch the *Daffodils*, and they crowd out the grass for half the season at least. Certainly a word of praise is due to *Orange Phoenix*, *Sulphur Phoenix*, *Von Sion* and the double *Incomparabilis*, not even omitting the double form of the Poet's *Narcissus*, though some one will probably tell you that it always goes blind and does not flower. Last year not one flower opened with us from newly planted bulbs; this year they are in full bloom with pure white double *Gardenia*-like flowers, fragrant and beautiful.

South Lancaster, Mass.

O.

Natural Varieties of *Narcissus Tazetta*.

NARCISSUS TAZETTA and its varieties, commonly known as *Polyanthus Narcissi*, are less hardy than most of the other species of the genus, but, with a single exception, there is no trouble or risk of loss in growing them in the open ground as far north as Boston. A light covering of corn-stalks or other material should be given, not for the sake of warmth, but to shade the ground and keep it from cracking down to the bulbs in the alternate terms of freezing and thawing which make up our winters. With such protection I never lose a bulb in the severest seasons. In sections where snow lies on the ground all winter no covering is needed. I advise the out-of-door cultivation of the finer varieties of *N. Tazetta*, the planting to be done at the end of October and the covering to be applied a month later; pot-grown specimens are poor compared with those in this way grown. I have this spring had eighteen flowers of *Grand Monarque* on a single stalk, each blossom nearly as large as those of *N. poeticus*. In its wild state *N. Tazetta* sports into many well-marked varieties, so distinct that some authors have regarded them as valid species, and many of them are figured as such by Jordan and Fourreau. I have cultivated many of these for several years, and offer here the observations I have made upon some of them.

N. Tazetta canaliculatus makes a slow and feeble growth, its longest foliage rarely exceeding nine inches, and the leaves are few and slender. The flowers, not more than four or five on a stalk, are small, their segments narrow and pointed. The color of the segments is yellowish white; the cup is light yellow. The bulbs are larger than those of some varieties of far stronger growth; they can be bought for thirty-five cents a hundred, a low price apparently, but far more than they are worth to a gardener, for this is the least attractive *Narcissus* I have ever seen. *N. Tazetta neglectus* is somewhat better in color and size, but is of little interest or beauty. *Patulus* is somewhat better, and *Siculus* is still another step upward in the scale of beauty, for in these the segments are clear, unstained white. They are, however, hardly worth growing, as far more beautiful varieties are obtainable. The form that is considered the type of *N. Tazetta* is quite attractive, though no larger than the other kinds named, for its colors are clearer and its form more graceful. *Tenorii* has comparatively broad petals and is very handsome; but the best of these Italian forms is *N. Barlæ*, which may claim equality of beauty with the best garden forms. Though not as large as some of these, it is exceedingly bright and beautiful, and its fragrance is less heavy than in most varieties of the species. *N. pachybolbos* is an Algerian kind which is ranked as a variety of *Tazetta*, though widely different from any other variety of this family. The bulb is very large and rough-coated, the foliage taller than is usual in the genus, and the flowers, pure white with light lemon cup, are very small and closely clustered. It is well worth growing for its distinctness, though it is somewhat tender and ought to have the protection of a frame. The variety *Papyraceus* is the Paper White of the florists, very pretty and early in flower, but now superseded by a seedling variety of the same color and larger growth. *Italicus* and *Obliquus* are varieties we can very well dispense with, especially the latter; they are little, if any, better than *Patulus*. Of *Beitoloni* I cannot speak; I have had it two years, but have not yet seen the flower.

I have tried seven or eight other wild varieties, most of them from Italy, of which there is nothing in particular to say. *Tenorii*, *Barlæ* and *Pachybolbos* are the only ones which have any horticultural value.

The Water-garden.

IT is very pleasant, these balmy June mornings, to be greeted as one's first glances turn to the garden by the beautiful *Nymphæas* gracefully anchored in the clear pool. In the early morning the water-garden is full of animation, the flowers expanding rapidly, the fish full of activity, engaged now in ap-

parent play, and then agitating the Lily-buds as they eagerly seize some tempting morsel. The abundant frogs are not very serious, and their antics fascinate the house cat, who keeps a constant and agitated watch by the borders of the tank. Every passing cloud adds a fresh charm as it is mirrored in the water, and the swaying of the grasses to the gentlest breeze completes the picture of beauty which we are more apt to associate with some wild scene than with a small city garden. Yet such a scene of quiet beauty is easily arranged in comparatively limited quarters, and is certain to be a constant pleasure. My friends who have become inoculated with the passion for aquatics seem to be thoroughly occupied by these plants rather to the exclusion of others. Devotion to one family of plants is well for the commercial grower, but is not the most satisfactory to the owner of a garden, who should ever have in view the enlargement of his sympathies. However, the field of aquatics is rather large, there being some threescore or more of *Nymphæas* and *Nelumbos*, with many and varied plants to associate with them, while there is an almost endless list of Grasses, Rushes and Irises, which naturally associate with a water view, while in quiet artificial bogs may be developed innumerable beautiful things. To any one who is fond of tender foliage, so enjoyable usually only in early spring, the water-garden offers an opportunity to gratify this taste, so seldom satisfied in the usually hard foliage of summer plants. On the whole, the cultivation of aquatics is not to be recommended to any one who fears to have his blood stirred by the collection of fine plants, many of which are rather difficult to secure, and a daily pleasure from constantly changing beauty. To any one who cares to try an interesting experiment, it may be said that it is not yet too late to start a water-garden this season. There are few spare ponds available in ordinary gardens, and it will be necessary to arrange an artificial tank or pool. Perhaps it is better at first to make a tentative experiment, and try only a small tank. This for a single Lily may be made of a half molasses-cask sunk in the ground, or a space may be dug out eighteen inches deep, and the bottom and sides plastered with a thin coating of Portland cement. Planted in rich earth the plant will soon make rampant growth and give a succession of flowers. It would be well perhaps to attempt a *Nymphæa Zanzibarensis*, because this is a plant of rapid growth which flowers all summer. Of hardy Lilies, *N. alba candidissima* is the most satisfactory and free-flowering, and *N. chromatella* has a fine yellow flower with the same qualities. Our native *N. odorata* and the red variety are scarcely satisfactory except in collections, as their blooming season is short. The Egyptian Lotus (*N. speciosissima*) is a plant of rare and striking beauty both in leaf and flower, and is easily grown, though its true habit does not appear in the illustrations of the catalogues.

Of course, the water-garden must be placed where it will have all the sunlight possible, warmth being necessary to the growth of the plants. A few fish are indispensable, to keep the water sweet. Hardy *Nymphæas* may be wintered successfully in this latitude in a shallow tank. My tank, twenty inches deep, was covered over last winter with boards and a slight covering of leaves. At no time, even in severe weather, did more than two inches of ice form, and probably, with a thick covering of leaves, the water would not congeal. The roots of my *N. alba candidissima* wintered with their crowns within six inches of the surface, and it is now strong, vigorous and full of flowers, though not replanted this season. The other hardy *Nymphæas* all came through unscathed, as did the *Sagittarias*, except *S. Montevicensis*, which was wintered in a cold tank at thirty-five or forty degrees. This is, however, too cool for this variety, and it evidently requires a temperature ten degrees higher than this. The same tank proved fatal to *Cyperus alternifolius*, though *Hedychium coronarium* wintered safely there, as did *Nymphæa Mexicana*. This *Nymphæa* I have reason, however, to believe may be safely dried off. *Aponogeton distachyon* was the first plant to bloom in my tank, it being hardy and moving at the first warmth. The season for *Nymphæas* opened on June 1st with the flowering of *N. alba candidissima*, followed quickly by *N. pygmaea alba*, *N. chromatella* and *N. Laydekeri rosea*. Numerous buds on the other varieties promise soon a wealth of flowers.

Elizabeth, N. J.

Notes from the Harvard Botanic Garden.

ANEMONE ROBINSONIANA.—This little plant is again in full bloom, and it has a very charming appearance in sunny weather, for it is only under such circumstances that the flowers expand fully. The foliage forms a close green carpet from six to nine inches high, and it is thickly studded with the pale

blue flowers, which are an inch and a half in diameter, and are borne on erect slender stalks three or four inches long. Dull or wet weather is exceedingly injurious to the blossoms, and causes them to close and decay prematurely. The plant is a form of the common *A. nemorosa*, and was first discovered in an English wood some years ago. It is perfectly hardy, and thrives well in partial shade, preferring a moderately dry situation and good garden-soil. It is seen to greatest advantage in a somewhat sheltered and lightly shaded position in the rock-garden, and it should never be disturbed unnecessarily. The groups that have been longest established are always the most attractive during the flowering season, however luxuriant those of more recent formation may be at other times.

CAMASSIA ESCULENTA.—The Camass, or Quamash, is now at its best. It has linear leaves of pale green color, and about a foot in length. The erect racemose scapes, from twelve to twenty-four inches high, are produced in great abundance, bearing along the upper portion numerous spreading bright blue flowers, two inches in diameter. The divisions of the flowers are keeled and of oblong form, and the yellow anthers, at the apex of filaments nearly equal to the segments in length, are showy for some time after the flowers open. It is an excellent plant for a partially shaded situation, and it also thrives fairly well in the sun. A deep, rich sandy soil is the most satisfactory, and the offsets of the bulbs afford a ready means of increase, as do the seeds. The latter ripen in summer, and should be sown as soon as possible after maturity. *C. esculenta* is a native of the western and southern parts of the United States, and it has been in cultivation as an ornamental plant since 1837. The roots are used as food by certain tribes of Indians, and it is said that bears are very partial to them. It is not perfectly hardy in this part of the country, requiring a moderate covering of leaves or dry litter in the winter months. *Scilla esculenta* is a name often given to this plant, but *Camassia* appears to be the more popular generic term. There is said to be a variety, *C. esculenta Leichtlini*, with white flowers and a more robust constitution. A plant with these characters would be extremely desirable, and I should like to hear something about it from any one who has ever grown it or has seen it growing.

PULMONARIA SACCHARATA.—None of the *Pulmonarias*, or Lungworts, are very common in American gardens, and this species is no exception to the rule. It is, however, well worth growing in a mixed collection. The height seldom exceeds twelve inches, and the habit is spreading, with branches freely produced, thus forming a neat plant for the herbaceous border or for planting with alpine. It is a thoroughly hardy perennial, and the stems are clothed with elliptical or oblong, alternate leaves. The lower leaves are generally narrowed down to a rather long petiole, while those above are strictly sessile. All are dark green, with a profusion of large and small spots and blotches of whitish color, which give them a decidedly curious appearance. The variegation, at any rate, is of quite an uncommon order among hardy plants, and more like the irregular kind so often found in tropical vegetation. The flowers appear in May and June, and are borne in compact terminal racemes of six or seven. They are five-lobed, somewhat spreading, and generally of a bright blue color. But here we have a rather interesting example of flowers of different colors appearing simultaneously upon the same stalk, as it is very common to find pink flowers and blue of the same age on a single stem of *P. saccharata*. This phenomenon, however, is not confined to *P. saccharata*. It occurs in several other species of the same genus, and invariably attracts attention. After the flowers disappear the leaves become larger, and their variegation becomes more intense. The plant retains this attractive appearance until late in autumn, the driest summer failing to affect it to any appreciable extent. It will thrive almost anywhere, but the variegation is brightest and it flowers best in a sunny position where the soil is not very rich. *P. saccharata* is a native of south Europe, and has been in cultivation upward of seventy years; it is propagated by division in early spring.

SCILLA CAMPANULATA.—The white form of this plant, known as the variety *Alba*, is now in bloom. It is the exact counterpart of the species in everything except the color of the flowers, which are pure white. There is another variety, *Carnea*, in which the flowers are of a beautiful pink shade. All three are natives of southern Europe, and they have been cultivated since 1683. Large patches of the three kinds in mixture make a handsome display, as they usually all flower at the same time. The margins of long stretches of shrubbery are much more beautiful in spring if care has been taken to give these plants a place in the border. In this case they are most effective when planted in clusters of the same color. The good

qualities of these plants are their complete hardiness and their satisfactory growth without the least attention after planting. Even in the grass of the wild garden they thrive and bloom year after year, and there is no situation in which they are more pleasing and effective.

STELLARIA HOLOSTEA.—European gardeners do not think much of this plant, presumably because it is quite common in many parts of their continent, including England. But there are some who give it a place in the garden, and their pains are well rewarded by its neat tufts of bright green foliage, which are completely covered in May and June by spreading snow-white flowers three-fourths of an inch across. *S. Holostea* lacks that character of weediness for which all other *Stellarias* are chiefly noted; and in this country especially its habit is more compact and the flowers are produced with far greater freedom than in its native home. This is doubtless due in some degree to the drier atmosphere and greater warmth of our spring and summer. The height of the plant under ordinary circumstances is about nine inches, but in dry places it is often much less. The opposite leaves are sessile and lanceolate. The tufts soon attain large dimensions, for the roots are of a creeping disposition, a fact which renders the plant extremely easy of propagation by division. It is an excellent plant for the front of an herbaceous border, preferring a sunny position and soil of medium depth and fertility. Some portions of the rock-garden suit it very well, and it is always charming wherever it can be induced to grow.

VERONICA GENTIANOIDES.—It is nearly one hundred and fifty years since this pretty Levantine Speedwell became known in gardens. The plant has creeping roots and is of erect habit, varying in height, according to soil and position, from six to twenty-four inches. The radical leaves are lanceolate, obtuse, from three to six inches long, smooth or slightly pubescent and of rich green color. The stem-leaves gradually diminish in size toward the top, and ultimately become mere lance-shaped bracts among the flowers. The flowers are rather more than half an inch across, and are borne in compact terminal racemes. They are very pale blue, with numerous lines much darker in color. It is one of the earliest species of the genus to flower, being in full bloom about the middle of May, and lasting well into June. No special care is required to grow it well, as it thrives in almost any soil or location, and the dense patches of verdant foliage impart a refreshing appearance to semi-barren spots during the scorching months of summer. The plants grown in shady places, where the soil is rich, are, of course, much more vigorous than those given poor soil and full exposure to wind and weather. There are many parts of the rock-garden in which it will be at home, for it is one of our hardiest plants, and a genuine alpine. There is a dwarf form with variegated foliage which is useful in formal bedding. Division of the roots is the most expeditious method of propagating both plants.

Cambridge, Mass.

M. Barker.

The Pear Psylla.

PEAR orchards in some sections of New York have been seriously injured by a small, sucking insect, commonly called the Pear psylla. It appears to be particularly abundant in the Hudson River Valley, but orchards in the lake-regions of the western part of the state have also been seriously injured. This insect was uncommonly destructive during the past year. At the Cornell Station experiments have been made to determine at what stage of its existence the pest may be most successfully treated. Mr. Slingerland, assistant in the entomological department, has had charge of the work, and has arrived at some interesting conclusions.

The Pear psylla, which did so much damage during the past summer, is probably a new species. In general appearance it closely resembles the cicadas or "locusts," but the mature insect is only about an eighth of an inch long. Mr. Slingerland found adult forms in crevices of the bark during winter and early spring, and it is probable that the insect passes the winter in this form only, as no eggs could be found. During April and early May these adults lay their eggs, generally near the ends of the smaller twigs. The eggs are very small, ovoid, and of a shining yellow color. They hatch in about three weeks, the time depending somewhat upon the weather. The young insect is quite flat. The insects soon crawl toward the extremities of the shoots and begin operations among the petioles of the young leaves or upon the young shoots. Some are also found upon the midveins of the leaves. These immature forms secrete a nectar or honey-dew in such quantities that sometimes the secretion in two days will be equal in amount to the bulk of the insects themselves. It is probable that the viscid substance which was so abundant upon affected

trees last year was not the sap of the tree, but was the secretion of the insect. Later in the season affected branches assumed a black, sooty appearance. The number of broods produced in a season has not yet been determined.

Mr. Slingerland has tried a number of insecticides for the destruction of the eggs and the immature forms. Eggs were dipped in several solutions, but even pure kerosene failed to kill them. It seems doubtful if the destruction of the eggs is practicable. The trees were sprayed with Riley's kerosene emulsion as soon as most of the eggs had hatched. A few days later fully three-fourths of the young insects were dead. This result is very encouraging. If further experiments verify the results, the Pear psylla is practically under control. It must be remembered, however, that this season has been exceptionally rainy, and the viscid substance in which the insect appears to delight in burying itself has probably been washed off as soon as it appeared, thus allowing the emulsion to reach the insect. Last year was dry, and during early summer it was utterly impossible to strike the pest with any applications. The fact that the young insect can be destroyed by the kerosene emulsion is, nevertheless, of the highest importance.

Correspondence.

The Color and Form of Houses.

To the Editor of GARDEN AND FOREST:

Sir,—Gratitude is due from your readers to Mrs. Robbins for recommending, in a recent number of GARDEN AND FOREST, the use of warm quiet colors in the painting of houses. In the article alluded to it is justly intimated that it matters little what may be the color of suburban and country houses in summer when surrounded by a wealth of foliage. But when the leaves have fallen, all defects of outline and all crudeness of tint come into bold relief in our clear, thin atmosphere. The house divested of its natural embellishments should, by the faultlessness of its structure, satisfy the eye as perfectly as does the architecture of the tree when stripped of its leaves. But this is far from being the case, and nature in America does not willingly cloak architectural frauds or blend inharmonious hues. The clouds, even, do not descend as in England, to envelop and give an added charm of mystery to form and color, and the Lichens, which mellow and adorn stone walls quite generally, hold themselves aloof from wood.

The house which requires to be painted is at best a makeshift. Although the wooden house may be cheap in the beginning, the annual expenditure for paint and putty, in the long run, makes it both expensive and unsatisfactory. It is therefore surprising that the thrifty New Englander should continue to endure this added strain upon his purse and patience; but there are men of whom it cannot be said "they builded better than they knew." On the contrary, they have, in a certain sense, built less well. It often happens that in youth the imagination is dazzled by a house more showy than beautiful, or, in spite of its defects, it may be endeared by home association. These recollections are lasting, the mind is haunted, and, as it were, pre-empted by them, and in a measure is cut off from receiving new impressions. It therefore follows in the course of time, when fortune is achieved and a plot of land bought, that the house intended to adorn it is constructed with reference to past standards of excellence rather than in accordance with present opportunities and knowledge.

Stone and brick are the appropriate materials for buildings. Their natural color is beautiful and suited to the temperature and atmospheric conditions of all seasons. The boulders which abound in every New England field furnish abundant material for country houses. In the hands of a skillful architect, when combined with unpainted shingles, they produce a grateful effect of solidity and repose. Such houses seem to have emerged by a natural process of growth from the earth itself, and harmonize with the landscape as no other colors or materials would. The vines which grow about them appear to be an integral part of the structure, and render other embellishments superfluous; nor is there the same need, as with frame-houses, for constant painting and repairing, advantages not to be esteemed lightly where there are so many petty cares connected with hasty workmanship and perishable materials.

Moreover, in the use of brick and stone it is almost impossible to be vulgar; at any rate, it requires a deliberate effort to be so. With wood, on the other hand, every architectural abomination is possible. The ease with which it is worked has rendered it the most available material for meretricious ornament; it has of late years fed the insatiate jig-saw and stimulated the already unbridled passion for the paint-pot. The

beaded-bed-post-broken-bottle style of architecture with which we have recently been afflicted has given unlimited opportunities for indulging perverted taste, and furnished an excuse for the use of the most varied and inharmonious tints. In truth, so far as color is concerned, there has been a veritable orgy which has put to blush the chaste green and white employed by the more circumspect builders of the past. Instead of striving for kaleidoscope effects, with our white lights and white heat, we should rather seek subdued and restful colors and all other tranquilizing influences to quell the feverish perturbation of our modern life.

Since the wooden house, at best, has a thin and unsubstantial appearance, it is all the more necessary to atone for these shortcomings by adopting such colors as suggest warmth and stability; the light browns and warm shades of grays are, therefore, preferable to the glaring yellows or frigid white which, during our winter months, make a house about as inviting a refuge as an iceberg. One would as soon expect a cup of tea or other warm civility at the hands of the woman who plays the zither in the ice-cave at Grindelwald as from the inmates of these chilly-looking mansions.

It should become a recognized part of the moral code that those about to paint should submit a choice of colors for the approval of residents in the immediate neighborhood, for the question of color is one of more importance to those who dwell without than within the house. By the neglect of this precaution the beauty and harmony of a whole street is often spoiled by applying to one house a color which is discordant with every other. If the prevailing tone is quiet and unobtrusive, the introduction of bright yellow or glaring white may become, by contrast, thoroughly obnoxious and irritating and a cause of complaint as well founded as that evoked by any other act of violence. It is said that once when Turner visited a gallery of pictures where one of his own was on exhibition, he found its beauties entirely obscured by the proximity of a painting much stronger in tone; he at once heightened the value of his landscape by adding a bright spot of vermilion, which completely annihilated everything in its immediate vicinity. This high-handed measure is perpetrated daily in inoffensive communities, where hanging committees are unknown, and therefore without the provocation which a Turner could claim.

As a rule, Americans do not seem to be endowed with a sense of color, and hitherto the public in this respect has received scant education at the hands of its natural preceptors, the architects. Until quite recently, as a class, they have lagged behind the intellectual advance of the nation, although there was never so golden an opportunity for men of this profession as that presented by this vast unbuild continent. It is true that the building of cheap houses for the multitude is not so inspiring as the construction of cathedrals, palaces and town-halls; nevertheless, the magnitude of the undertaking ought in itself to have stimulated and engaged the highest talent of our people. It is computed that the cost of providing house-room for the increase of population alone will in 1893 reach the large sum of \$192,000,000.

The present architectural awakening gives assurance that the millions destined for future building purposes, in the older parts of the country at least, will be tolerably well spent; but there are immense tracts of land which lie open to the spoilers' hand. The jig-saw has already commenced its direful work south of Mason and Dixon's line, and pea-green houses bear witness to the so-called "march of progress." There is, however, some consolation in believing that the license which the builder has hitherto allowed himself in the handling of wood may in the end, when this accustomed freedom is held within bounds by discipline and self-restraint, redound to his glory and enable him to give breadth of treatment in his use of more enduring materials.

Cambridge, Mass.

S. P. S.

A May Outing.

To the Editor of GARDEN AND FOREST:

Sir,—The enjoyment of the spring-time is largely a matter of imagination and of anticipation to one who lives in the city, and who sees the return of spring only in the budding of street trees and in the grass upon the open space about some of the houses, while he waits for a chance holiday for an outing in the fields and woods.

Holidays are all the more enjoyable on account of their rarity. Of them all Decoration Day is the best, for Nature has now done her decorating, and no luxuriance later in the season can increase the beauty of the flower and foliage of this time. Wild flowers are abundant, and even the aristocratic Orchids are

largely represented among the native flowers that grow around this Urbs in Horto.

In a wood principally of low Scrub Oak, we found on last Decoration Day a great many Lady-slippers (*Cypripedium parviflorum*) growing luxuriantly and in full bloom. To compensate for carrying away the roots of some of the plants, we fertilized a number of the blossoms of those we left, so as to make sure of a crop of seeds for next year independent of the visits of any insects. Some of the poorer kinds of *Habenarias* were near by, and about a mile distant we found *Cypripedium pubescens* blooming on the open road-side without any shade whatever. These flowers are a brighter yellow than those of *C. parviflorum*; they are larger and deliciously fragrant, suggesting the aroma of apricots.

A small boy offered to show us where the "red ones" (*C. acaule*) grew, and also to take us to fields of the little white-flowering *C. candidum*, of which he had a quantity of the blossoms. He also knew where the large white and pink flowers of *C. spectabile* would be in bloom in a few weeks. The little Ram's-head (*C. arietinum*) is sometimes found here. This makes a list of six *Cypripedium*s natives of this locality.

Besides the *Cypripedium*s there were blue Lupines, the bright scarlet and yellow Painted Cups, the pretty little yellow stars of *Hypoxis erecta* and the pink *Phlox pilosa*, of which a beautiful pure white specimen was found; many other floral treasures added interest to our day's outing, all too quickly passed.

Chicago.

American Species of Ash.

To the Editor of GARDEN AND FOREST:

Sir,—It will, perhaps, be interesting for the readers of GARDEN AND FOREST to see what I consider the exact list of the species of *Fraxinus* of the New World. It is the one which I have adopted in my monograph of *Fraxinus*, read before the Royal Botanical Society of Belgium at the meeting held on May 1st. My reason for asking you to publish it in your interesting and learned journal is, that I may make known to American botanists my understanding of the American species, and to obtain their criticism upon my observations made in the principal herbaria of Europe. My idea of the limitation of the species in the genus *Fraxinus* has compelled me to reduce considerably the number, which is more than a hundred; and I have reduced those of the United States to five, admitting, however, a certain number of sub-species. This conclusion, based on a profound study of the fruits and leaves of all available material, will, perhaps, appear reactionary to many botanists, but it is only after having seen a great deal that I have arrived at my conclusions.

I shall be very glad to arrange to exchange specimens of the ligneous plants of Europe for those of North America.

AMERICAN SPECIES OF THE GENUS FRAXINUS.

Wing of the Samara, not prolonged to the base.

I. *F. SCHIEDEANA*. Schlecht et Cham.

II. *F. AMERICANA*.

1. Sub-species: *Typicum*.

i. Variety: *Normale*—*F. Americana*, L.

1. Sub-variety: *Discolor*, Muhl.

2. " *Acuminata*, Lamk.

3. " *Epiptera*, Michx.

4. " *Pistaciæfolia*, Torr.

2. Sub-species: *Novæ-Angliæ*, Mill.

i. Variety: *Berlanderiana*, DC.

3. Sub-species: *Pennsylvanica*, Marsh.

i. Variety: *Longifolia*, Vahl.

1. Sub-variety: *Aucubæfolia* hort.

ii. Variety: *Sub-pubescens*, Pers.

iii. " *Latifolia*, Willd.

iv. " *Rubicunda*, Bosc.

4. Sub-species: *Oreganæ*, Nutt.

Alfred Wesmael.

Hardy Plants at Passaic, New Jersey.

To the Editor of GARDEN AND FOREST:

Sir,—I went over to Passaic, New Jersey, a few days since to see the early summer flowers in Woolson & Co.'s Nursery. Pæonies are widely distributed plants, but it is only in a nursery where they are grown by the acre that the full effective-

ness of their massive flowers may be seen. An acre of these plants in flower, though planted in nursery rows, makes a wonderful glow of color on a bright June day. From the very extent of the view the flowers lose somewhat of their solid individuality, and one is half-intoxicated with the barbaric wealth of color above the foil of ample foliage. The ordinary Pæonies of the garden are apt to be washy purples or blue-reds, which jar with the orange and scarlet flowers of the same season. It was pleasant to see that such colors are very rare in this nursery, the more modern pink, rose, salmon, blood-red and white varieties seeming to comprise the majority of the collection. The single varieties of Pæonies are very taking, with their comparatively light, yet large Anemone-like flowers. Albiflora is a good one of these; the color is rather variable from white to a delicate rose, with a bunch of golden stamens. Baron James Rothschild is another form, semi-double, showing the stamens, and of a good pure pink. Of the massive double varieties I fancied Blanche, pure white, Rubra Triumphans and Proserpine, both very dark, clear blood-red. Of the rose and pink varieties, mostly with broad petals and full centres of narrower petals, a very effective form, some of the best were Hercules and Duke of Wellington, with blush guard petals and white inner ones; Rosa elegans, blush; Reine des Roses, guard salmon, centre flesh color; Cydonie, rose, very large guard petals; Plenissima, pink. Of the newest varieties under trial two extra fine ones were Mire de Soufflé, with white guard petals and distinct sulphur centre, and Charles Toche, semi-double, of a deep clear bright rose. Colors of Pæonies do not admit of strictly accurate description, as they vary according to the age of the flower. It is possible to have a long season of Pæonies, for the Moutan and tenuifolia varieties are past before the first of the common herbaceous kinds open. Of these there are a number of kinds just budding, which will extend the season a fortnight longer. L. d'Estrees, Monsieur Bonquiel and Delachei were noted as some late kinds.

The stretches of German Irises were the next plants of interest. These, of course, lack the brilliant effect of the Pæonies, but form unique colors in mass, while they are very interesting individually, and many extremely handsome. German Irises, so called, are simply bearded kinds, mostly hybrids of half a dozen species, and the great number of kinds grown by the florists can be divided into that number of sections. The varieties of these sections, which vary more or less, have the same general form and coloring. The old purple Flag is known everywhere; a deeper-colored variety is D. R. Parnot. Iris pallida seems to me one of the best of species for the garden. The plant has broad leaves and a bold habit, and the large fragrant flowers are light lavender, with orange beard. The hybrids are also very attractive. Zephyr, a very light lavender with graceful habit, William III., heliotrope, and Queen of May, rose, are all distinct. The varieties of I. aphylla have mostly white standards and falls flaked blue or rose. Madame Chereau is a well-known handsome kind. The varieties of I. neglecta have mostly lilac standards and falls of purple or purplish crimson reticulated white. Fairy Queen and Cythere are good samples of this section. The bronze and smoky varieties are descendants of I. sambucina or I. squalens. Victory, Violetta and Leopard are good examples of these. I. variegata is an effective yellow species which has given many handsome and useful varieties, mostly with yellow standards and reticulated falls, browns and deep reds. Striata, Cerberus, Jenny Lind and Monsieur de Lesseps are distinct kinds of these. Among the numerous true species of Irises now in bloom very few are effective, though they are interesting garden-flowers, but a group of I. orientalis showed a splash of very effective purplish blue. Some of the Japanese Irises were in bud, and these will closely follow the German Irises, prolonging the season through June and early July.

There are always many interesting things in a large collection of hardy plants, but when one passes from the general favorites or certain families one rather hesitates to recommend even striking plants, since the satisfaction to be derived from many depends so much on the special taste of the grower. No plants require to be more carefully selected, and frequent visits to nurseries are essential to a satisfactory selection of unknown things. Still I noted many favorite plants in flower. The Pinks were represented by broad stretches of Dianthus atrorubens, D. deltoides, D. plumarius, etc. At this time the yellow Day Lilies (Hemerocallis) are seen in great masses. Our old friend, H. flava, is clear and pure, but not as effective as the orange variety, H. Mittedorfiana. Of the Plantain Lilies, grown in great variety, the newest is Thomas Hogg, which struck me as a very distinct kind, with broadly margined leaves.

A hardy garden is not complete without Rosa rugosa, which

is so extensively grown, but its beauty as a screen or broad hedge never appeared to me so forcibly before as I saw it here in a solid row some hundreds of feet long of large plants, with the wealth of beautiful dark green foliage, which was a picture, without the attractive flowers. But the picture I carried away with me with the greatest pleasure was that of a mass of Rosa rubrifolia, a Rose with stems and foliage of a lustrous soft red. Furnished as it is at this season with the lovely single flowers, it is a treasure for any garden.

Recent Publications.

The Oak: A Popular Introduction to Forest-botany. By H. Marshall Ward, F.R.S. New York: D. Appleton & Co., 1892.

This is the third volume in the Modern Science Series, edited by Sir John Lubbock. The plan is quite similar to that of the International Scientific Series, but the works are intended to be less technical. This volume is a neat and well-made book of a hundred and seventy-five pages, illustrated by two plates showing the English Oak in summer and in winter, and more than fifty figures in the text showing points of structure. The eleven chapters treat of germination; the seedling and tissues, tissue systems and organs; the tree—its root, stem, flowering and fruiting organs; oak-timber, cultivation, diseases; relationships and distribution in time and space.

The story of the Oak in this logical sequence is told with considerable fullness and with few technical terms, but, after all, it is by no means light reading. To write an interesting book on microscopic structure for laymen is not an easy task. From most points of view this work has been successfully accomplished by Professor Ward, but it must be admitted that the style is rather heavy and monotonous; that the main facts do not stand out from the mass of details in sufficiently strong contrast, and that their relationships to each other are not made sufficiently clear. Even the botanist will find that close attention is required if he is to get an adequate comprehension of the work. The author dwells briefly upon gross structure, and proceeds almost immediately into the microscopic characters, and holds to this treatment almost throughout the book. These objections are mentioned because the book is offered for the general reader, who is not properly equipped for the task set before him. The language used is very condensed, every chapter is full of facts, and the careful student may gain from them a good knowledge of the structure, growth and fruiting, not only of the Oak, but of the entire class of dicotyledonous plants. The chapters on structure are too full to be summarized here. They describe the various kinds of cells and tissues as they exist in both young and old plants. The leaf-trace and the arrangement of the fibro-vascular bundles are explained. The suggestion is made that the symbiotic mycorrhiza, which seems to perform the office of root-hairs, may possibly be mycelium of the Truffle. The fact that Oak-woods are the special habitat of the Truffle would tend to strengthen this view. The chapter on Oak-timber treats by paragraphs of appearance and structure, density, water and drying, swelling, elasticity and tenacity, flexibility, torsion, splitting, hardness, durability, burning properties, peculiarities, uses. Under "Durability" we learn the interesting facts that a piece of oak-pile taken up from a London bridge in 1827 had lasted for 650 years, and that another piece from the Tower of London was probably put in when the Tower was built.

Under "Cultivation" is an interesting statement, credited to Hartig, that Beech-trees store up nitrogenous materials and salts for seventy or eighty years, then suddenly yield them up in an abundant crop of seeds. This is such an exhausting process that three to five years are required to accumulate materials for another crop. Is the alternation of bearing and sterile years in fruit-trees to be similarly explained?

Various insects and fungus enemies of the Oak are referred to, and a number of the latter illustrated in their effects by figures from Hartig. The closing chapter sets forth the abundance and wide distribution of Oaks in the northern hemisphere and the great antiquity of the race.

Notes.

By an annoying oversight *Ascyrum Crux-Andreae* was called *Asarum* in our issue of June 1st, and the error was repeated in the text of the article describing it.

The Virginia Fringe-tree (*Chionanthus Virginica*) has been in flower for more than a week, and it is as attractive as ever. This is one of our smaller native trees which, taken together with our Cornels, Viburnums, Thorns and Sumachs, make a

group unsurpassed in beauty by any similar collection from any part of the world.

An annual scholarship in botany has just been founded at Barnard College for young women by a benefactor whose name has thus far been withheld.

Mr. J. W. Menzies has calculated that the price paid to France by the United States in 1803 for the region which now forms the state of Louisiana amounted to one penny and one farthing per acre for land most of which was of high fertility.

According to a report of the United States Minister at Stockholm, the greatest source of revenue to the kingdom of Sweden is its forests. That portion of the country which is called the Norland is still, for the most part, covered with extensive forests largely composed of Pine and Spruce.

Miss Clara E. Cummings, of Wellesley College, Wellesley, Massachusetts, requests us to make known that she can supply copies of the catalogue of the Musci and Hepaticæ of North America north of Mexico at the greatly reduced price of twenty-five cents each, postpaid. It is based upon the *Manual of Mosses of North America*, by Lesquereux & James, and the *Descriptive Catalogue of the North American Hepaticæ*, by L. M. Underwood.

The China Aster, which is the most popular of summer flowers in France, and is there called the Reine Marguerite, was introduced into that country about the year 1730 by the famous Jesuit, Father d'Incarville. "To-day," says a recent French writer, "there are more than twenty distinct strains of China Asters, and as each includes from three to twenty different colors, it is no exaggeration to affirm that there are more than two hundred distinct varieties of this beautiful flower."

Mr. T. D. Hatfield writes to commend a variety of Phlox subulata, which was selected as a seedling from the form known as The Bride, and which has been named Sadie. When all the other Moss Pinks are past this one is still in full bloom. It is a clear blue, and much better than the only other blue dwarf Phlox (*P. stellaris*). He also states that there are three varieties of the true bedding Violets which come tolerably sure from seed and take care of themselves in the rock-garden, which seems quite as appropriate a place for them as the border. These varieties are known as Snowflake (white), Yellow Gem and Perfection, both of which are purplish.

Some members of the Agassiz Association, at Forreston, Illinois, having observed that the plow and spade, with the reaper and mower, had been driving many of the wild flowers from their native haunts into byways and fence-corners, where they easily fall a prey to rooting swine or reckless plant-pullers, have established an asylum for these hunted children of the woods, and will attempt to preserve them from extinction. Spring Beauty, Painted-cup, Trillium, Bloodroot, Dicentra, and many other flowers which are threatened with extermination have been gathered into this garden of refuge, which, we have no doubt, will grow in interest and usefulness for many years to come.

An idea of value now set upon large estates in Great Britain may be gathered from the recent sale of Craig Castle, in Aberdeenshire, Scotland, which is described in *Truth*, of London, as "a fine sporting and residential estate," extending over 4,640 acres, and consisting of "an excellent house with beautiful grounds, which include the picturesque Glen of Cray and the celebrated Buch of Cabrach." The price given for the whole property was only £33,000, not more than some Americans have paid in establishing what they call mere "villas" at Newport. The castle had belonged to the family of the Mr. Gordon, who has just disposed of it, since the year 1499, and Mary Queen of Scots signed the warrant which confirmed its possession to the son of the original grantee.

It is good news for the poor of our city that protected areas along the river-fronts are being arranged to afford them fresh air and comparatively quiet places of repose. The pier at the east foot of Jefferson Street is at once to be shedded and the roof railed about for a free promenade; and the large pier at the foot of West Thirty-fourth Street is to be fitted with an awning and rows of benches, and will be thrown open to the public about the middle of June. Each of these places, of course, commands a wide prospect of blue water, and from the latter one the splendid panorama of the western banks of the Hudson is revealed; and the lack of green and growing things in the foreground will be partly made good by the free sweep of an air much cooler and fresher than that which circulates through parks in the heart of a town. The way in which

the poorest classes of the city through the piers in midsummer days and nights, even when no roof protects them and no seats welcome them, should inspire our authorities to establish as many as possible of these novel breathing-spaces.

Florists who force Bermuda Lilies naturally wish to get the bulbs as early as possible, and to meet this demand the growers have been digging them earlier each season, until the practice of shipping before they have sufficiently matured is not uncommon. Messrs. Peter Henderson & Co. have been writing to some of the florists who force this Lily on a large scale to ascertain their opinion as to the value of these unripe bulbs. Men who have experience in forcing, like Robert Craig, I. Fosterman and James Dean, give emphatic opinion as to the necessity of leaving bulbs in the ground until they are thoroughly ripened. Mr. Craig states that the early bulbs, which are soft and flabby, do not root well. Mr. Fosterman adds that the flowers from such bulbs do not keep. Mr. Dean says that the earliest bulbs have a flimsy texture, and when used for early forcing will either come blind or have many imperfect flowers. He adds that a bulb fit for forcing should be a bright yellow color, with the scales hard and of good substance. If left in the ground until thoroughly ripe the scales will have covered the old flower-stalk.

Monsieur Gadeau de Kerville is now publishing a large book on the ancient trees of Normandy, which is described as being very interesting. Among the remarkable specimens which he has thus far noticed are two Yew-trees which stand at La Haye de Routot, in the Department of the Eure, and which he estimates to be not less than 1,500 years old. The larger of the pair measures nine and a half metres in circumference at the base of the trunk and seventeen and a half metres in height, while the other girths eight and a quarter metres and is fourteen and a half metres tall. In the hollow trunk of one forty persons have sometimes gathered, and concerts have been given by eight musicians; but it has now been transformed into a chapel, which is ten feet high and nearly seven feet in diameter. At Montigny, says Monsieur de Kerville, stands a famous Beech-tree which must be between six hundred and nine hundred years old, and is eighteen metres in height and eight and a quarter metres in diameter. Some of the Oaks which he describes he believes to be from two hundred to nine hundred years old, and one of them is forty metres in height.

Most persons are familiar with the prettily marked stones which are called "moss agates" and which appear to contain perfectly preserved bits of a moss-like vegetable growth. It is commonly believed that such agates and other similarly marked stones, grouped under the name of dendrites, really contain fossilized plants; indeed, both of these names bear witness to the antiquity and generality of the mistake. As Monsieur Stanislas Meunier recently explained in an article called "Dendrites," published in *La Nature*, "it is easy to discover that dendrites have none of the characteristics of the vegetable ramifications with which we are inclined to compare them; and when we study them under a sufficient magnifying power, the crystalline structure of the greater number of them is very distinctly apparent. Particularly is this the case with the black dendrites which are most common and which I have studied with especial care and have succeeded in producing artificially. It is plain that these dendrites, consisting of a hydrated oxide of manganese, result from a precipitating action exercised by calcareous rocks on water containing traces of metallic salts."

From a recent issue of the *Revue Horticole* it appears that Monsieur Maxime Cornu, Professeur de Culture at the Jardin des Plantes, at Paris, exhibited before the National Society of Horticulture of France a flowering specimen of *Incarvillea Delavayi*, one of the new plants sent by the Abbé Delavay from Yunnan. It is a perennial plant with tuberous roots, dark green denticulate leaves, and handsome rose-colored flowers, which resemble in form those of *Tecoma radicans* and which last for a week without fading. In the climate of Paris *I. Delavayi*, like the other plants introduced from Yunnan, requires the protection of a cold house or of a frame. Other plants introduced into cultivation from the same country by this intrepid traveler and distributed from the Muséum are *Thalictrum Delavayi*, a beautiful species with blue flowers, *Primula calliantha*, *P. Poissoni*, *Kœlreuteria bipinnata*, a real addition to handsome small trees and remarkable for its enormous leaves and long clusters of flowers, although, unfortunately, not hardy in the northern states, *Rhododendron Bureari*, *R. cilicilyx*, *R. decorum*, *R. fastigiatum*, *R. lacteum*, *R. racemosum*, *R. Yunnanense*, *Berberis pruinosa*, *Desmodium longipes*, *Indigofera Delavayi* and *Desmodium pendulum*.

The Plan of the Columbian Fair Grounds.

MORE than twenty years ago a design was prepared by Messrs. Olmsted, Vaux & Co. for laying out three tracts of land which were known together as South Park, Chicago. One of these tracts is now Jackson Park, the site of the Columbian Exposition. Among the striking features of this plot of land, as pointed out in the report accompanying the plan alluded to, was its long frontage on the lake, which, in the opinion of the designers, added an element of such grandeur and sublimity that it compensated for the absence of picturesque elevations of surface, while at the same time it provided means of transportation by water from the city, whose business centre was some seven miles away. It was stated further that one-third of the surface of this land lay below the high-water level of the lake, and that a great part of the remainder was too low, too wet and too cold to maintain upland trees, while adequate drainage was nearly impracticable. It was suggested, therefore, that excavations should be made in the more depressed portions of this area and that the material taken out should be used to raise the adjacent ground above the lake-level, and that a free outlet should then be made through the beach to admit the water of the lake into a central lagoon, with various branches and ramifications, so that the element of water would be the most prominent one in the park. The commanding exterior feature would then be the lake, with its storm-beaten shore, and within would be the intricate and sequestered scenery of the lagoon, all its parts connected together and with the lake by a continuous stretch of water.

When it was finally decided that the Columbian Fair should be held in Jackson Park this scheme of inland waterways was taken as the fundamental idea of the general design. The ground was still unimproved, and it lay, as it had lain for centuries, in a series of ridges and hollows as the sand had drifted up in successive waves. The hollows were spongy swale lands, and it was determined to dredge

out enough of the light soil from them to make waterways of sufficient breadth and depth for convenient transportation and wide enough to form a feature in the scenery, while the earth which was removed would suffice to make a foundation for the stately buildings to be reared on their banks and lift them some ten or twelve feet above the high-water mark of the lake. In working out this plan more than a million cubic yards of earth have already been removed. The interior waters have an area of more than fifty acres, and provide a circuit of three miles for electric omnibus-boats.

The direction of the lake shore dictated the line of the buildings, and, of course, controlled the direction of the canals, and, in a measure, the shape of the lagoon. The largest building, that of Manufactures and Liberal Arts, an immense structure, which is fully a mile in circuit, is placed (see map on page 291) nearly on the centre of the lake-front and directly facing it. Since the southern face of this building forms a part of a great quadrangle, the other buildings, whose façades form the remaining part of the enclosure, are built on the same parallel lines. Extending from the lagoon and following the line of these buildings is a walled-in canal, which opens into a larger basin of the same formal character set at right angles with it. This basin also connects with the harbor and occupies the central and most important part of the quadrangle. The quadrangle itself, which is 2,000 feet long and about one-third as wide, is intended to serve as the grand hall or court of entrance to the Exposition both for those who come by rail and by water, and it is a magnificent architectural conception, and even now presents an imposing spectacle. The cornices on the great buildings which form its northern and southern boundaries are uniformly sixty feet high, while toward the lake a double colonnade, or peristyle, of the same height as the buildings, will carry on the cornice line, and give the whole an impressive unity. Toward the landward end of the Plaza the Administration Building, which is the loftiest and most strictly monumental building upon the grounds, rises from a base 260 feet square, and is crowned by a dome which reaches a height of 270 feet above the pavement. The four-story pavilions at the corners of this majestic structure are carried to the same height as the faces of the other buildings, making the cornice line sixty feet high continuous about the Plaza. Visitors who come by rail would pass through the arches of this stately structure into the quadrangle, where their first impressions of the Exhibition will be received. A glance at the map will explain to some extent this arrangement, and the magnitude of the scale upon which the whole idea is worked out will be understood when it is remembered that the basin contains nearly nine acres of water.

This plan of ushering visitors into the grounds through a porch of such dignity and into a court surrounded by architectural splendors, instead of letting them in through some side-entrance, so to speak, seems to us one of the finest inspirations of the design. No group of buildings approaching these in magnitude or of equal ambition in design, and related to each other so intimately, has ever been constructed in the entire history of architecture, and while the designers of the separate buildings have been allowed certain liberties as to details of expression they have worked together in perfect sympathy to secure a single consistent and harmonious effect. Of course there is little opportunity for anything like gardening in this Plaza. The ground on either side of the basin rises in successive walled terraces to the steps which descend from the colonnaded fronts of the building. The promenades are of sufficient width to accommodate the throngs of visitors who are expected, but there are some stretches of greensward in which are four sunken panels to be decorated by large specimen plants or statuary, and there will be space for shrubbery and flowers upon the lower terraces and against the walls. There are ample ways for communication between this Plaza and the buildings on either side

of it, and means of transportation to distant parts of the ground. To those who choose to go by water, a view from the boats in the basin of the buildings above, crowned with spirited groups of statuary and countless flags and banners bearing appropriate devices and in harmonious colors, will be particularly striking. At night the Plaza will be illuminated by search-lights from the square campanile on the lake-side, and all the walls will be treated with rows of incandescent lights along the cornices as well as the upright lines of the building and the ribs of the aspiring dome of the Administration Building. Lines of the same lights will also be arranged along the edges of the terraces and under the coping of the basin-walls, so that the entire plan will be outlined and present a scene of unexampled brilliancy, showing to advantage not only the general architectural features which we have mentioned but illuminating also the great statue of the Republic and the colossal works of allegorical sculpture which, with fountains and rostral columns in harmony with the classic character of the architecture, are massed here in lavish abundance.

In contrast with the elaborate and ceremonial treatment of this Plaza, the grounds to the north of the Buildings of Electricity and Mines open out to embrace the lagoon, which is an irregular waterway flowing about a large island, or rather a cluster of islands. The primary purpose of this island is to add a touch of breadth and natural openness to the scene and give a sense of some informality and repose in the midst of the prevailing activity and bustle. The larger island was originally high enough above the water to support some moderate-sized trees, and others have been planted to make a mass of foliage, over and through which the buildings surrounding the lagoon appear to great advantage. To secure the highest effect it was absolutely necessary that this island should be green to the water's edge, and as the time for preparation is so brief it was necessary that the planting should be made on an absolutely different method from that which would be employed in a permanent work—that is, plants were used primarily for their quickness of growth, and they were set as thickly as they could stand. Immense numbers of Willow-cuttings and shrubs of rapid development have been planted on the banks; and on the immediate edge of the island, where the natural rise and fall of the lake would leave a raw line under ordinary circumstances, plants like Rushes and Sedges and Flags and others which grow even when their roots are under water, have been selected. Great quantities of herbaceous material have been cut in sods from the edges of natural lakes near the city, and brought by the car-load to serve this purpose, and already they are beginning to produce their effect, while in the little coves and bays the Water-lilies are now spreading their foliage and opening their flowers, so that there is little doubt that the ideal of the designers will be realized next year.

That part of the grounds north of the lagoon will be occupied by the reservations for buildings of the various states and of foreign nations, and for our present purpose will need no explanation beyond what the map affords. Indeed, we have only attempted an outline sketch of the general features and leading motive of the design. Very little, indeed, can be said of the horticultural work now while the grounds are being graded and excavations made in preparation for the elaborate system of sewers, water-supply, electric wires and compressed air, not to speak of the necessary foundation for roads and walks. These constructions are of the first importance, and the surface is covered not only with material, but with engines and temporary constructions for the contractors. As the work progresses it is our purpose to give attention to its special features and illustrate from time to time the progress and completion of any of the work as it may prove interesting or instructive to our readers. Some of the more striking incidents of the design will not escape the attention of those who give any study to the plan, and without such a study the im-

portance of this artificial water-system will hardly be appreciated. It will be seen that every one of the prominent buildings is provided with a water-front, so that visitors can be carried in omnibus-boats propelled by electricity from any one to all the other great buildings in the grounds. Some views of conspicuous interest can also be readily imagined from a glance at the map. For example, from the southern end of the canal between the buildings devoted to machinery and agriculture, where there is a colonnade and obelisk, there is a direct line of water for a mile northward to the Art Gallery, and from the bridge near the Illinois State Building the view southward over the waterway and between shores clothed with verdure will be singularly attractive. A similar view can be had either to the north or to the south over the western branch of the lagoon. From the same bridge just referred to the view across the water to the Art Gallery, which, of all the buildings, is perhaps the one nearest perfection in its classic proportions, will be a favorite one. Looking from the island southward between the Buildings of Mines and Electricity the lofty Administration Building will appear to singular advantage; and the presence of the lake, even where it cannot be seen, is always felt as an element of unailing interest. The crowds who pass through the Administration Building when they enter the grand court will catch a glimpse of the lake between the columns of the peristyle and through the triumphal arch in the centre of this great colonnade. But the view of the lake will perhaps be enjoyed most generally from the eastern front of the main building, especially in the afternoon, when this will be in shadow. Ample space for promenade and seats for those who wish to rest, with covered booths and refreshment-tables, will be provided here and thousands can enjoy the coolness and beauty of the outlook.

A Rural Cemetery.

IN contrast to the formal grounds and showy gardening with stiff beds of foliage-plants and gaudy blossoms, which disfigure many well-known cemeteries, the restful spirit that characterizes Walnut Hills Cemetery, in Brookline, Massachusetts, is most grateful. Under the management of careful trustees, the arrangement of trees and shrubbery has been made to assume as natural an appearance as is possible in such a spot. The drives wind under the Oaks and Walnuts and Maples in soft and pleasing curves, while the shrubbery and undergrowth simulate the natural product of such sequestered woody places.

Nothing glaring or incongruous distresses the eye. The tomb-stones are modest and unpretending, many of them of slate or sandstone or granite, which harmonize agreeably with the natural features of the scene, and sometimes a name engraved upon a boulder is the only monument of the sleeper in the smooth grassy space below. There are no divisions between the different lots, no raised mounds to indicate the grave. The turf is closely clipped and green, the wild shrubbery clusters round it, the birds sing overhead, and the effect is sweet and solemnizing, as it should be in man's last resting-place.

The trustees control all the planting; this influence, though it may appear arbitrary to some, and I have been told is often unpopular among those who do not fully grasp the underlying idea, produces a result which could never be attained but by some intelligent governing taste, which subordinates detail properly to the general effect and prevents that shock to the eye which is so frequently felt when a mistaken zeal introduces some feature, good in itself, which conflicts with the main scheme. No planting is permitted here without the previous approval of the trustees, and the design of the tomb-stones must also be submitted to their wise and severe taste before being placed in the grounds. To those who have no especial design to offer, carefully prepared drawings are submitted of various unpretentious stones from which they may make a selection. Some of these designs have been illustrated already in these pages (vol. iii., p. 193), and are of quaint and pleasing pattern, after old Celtic or Norman ideas.

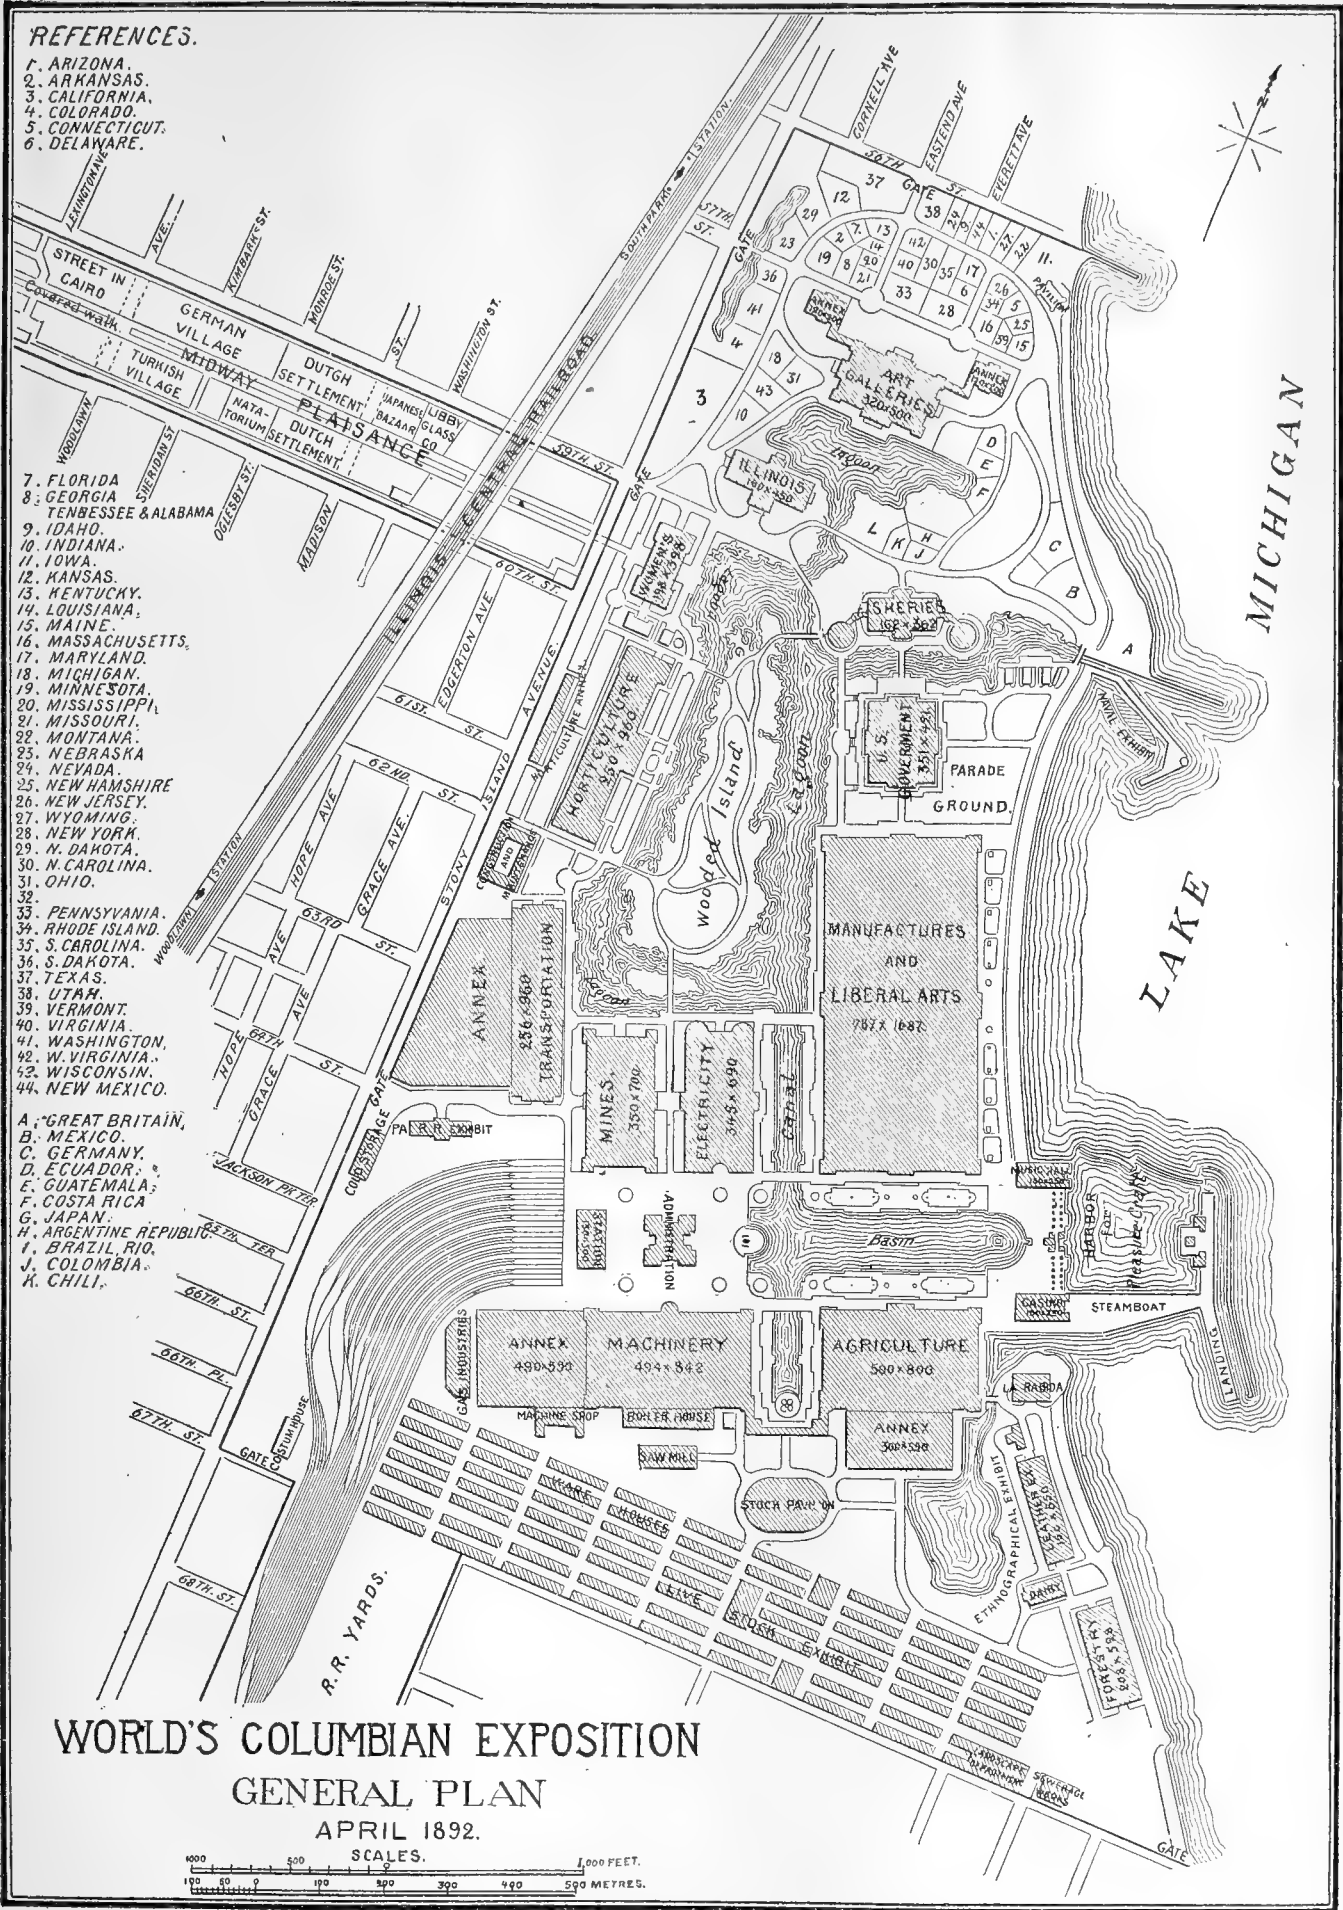

The effect of a simple slab, or of a Norman or Gothic cross, is very grateful to the eye, while a stiff obelisk violates one's sense of the beautiful and destroys the effect of repose, which

WORLD'S COLUMBIAN EXPOSITION

GENERAL PLAN

APRIL 1892.

SCALES.

is, after all, the impression one would most naturally wish a burial ground to produce. This effect is left on the mind by this beautiful condition, though some of the canons of art have been violated, even here, by a lack of strictness in the rules in the beginning. An air of serenity and rest for the sleepers pervades the quiet spot. Here the mind naturally turns to reflection, and nothing distracts it from those sweet and serious thoughts which best befit the last home of those we love. There is no consciousness of display, no showy cenotaph to inspire curiosity; all is dignified, unpretending and appropriate. In this, as in the Quaker grave-yards, one feels satisfied that nothing is done for show, but reverently, and with a desire that, in this last home, no man shall overtop his fellow with show of monument or brilliant floral adornment of his grave, but that here all shall be equal in the simplicity and dignity of Death.

Hingham, Mass.

M. C. Robbins.

Weeds in Southern New Jersey.

HOW quickly and how completely cultivation transforms the face of a country and brings on an entirely different class of plants or weeds from those which for ages upon ages had occupied their places before man came with his implements of husbandry to scarify the ground, has been strikingly shown in the recent history of this part of the country. It is only about thirty years ago since clearings were first made in the dense forests here, and for the past twenty-four years I have lived here and watched with interest the changes wrought in the flora. The native flora of southern New Jersey is most beautiful and varied. Some rare and local plants are found here, like *Helonias bullata* and our charming *Pyxidantha*, and it was thought for a long time that our little Fern, *Schizæa pusilla*, was found nowhere else in the world. The *Xerophyllum*, too, is partial to the damp sandy barrens, as well as many beautiful Orchids, among which are *Pogonia divaricata* and *P. verticillata*, with *Arethusa bulbosa* and the yellow-fringed Orchis, and the white-fringed and the pale yellow-fringed *Habenarias* and others. In common with New England and other sections, we find the *Trailing Arbutus*, the *Wind Anemone*, and the little *Star-flower*, the *Partridge-vine* and the *Pitcher-plant*, with others, all shy and retiring in their habits, never making any effort to hold the ground a single season after the plow and harrow have lacerated it.

But there are other plants which do not yield their places so readily, notably members of the Pulse family, like some of the *Desmodiums* and *Lespedezas*, the *Wild Indigo* (*Baptisia tinctoria*), the *Lupine* (*Lupinus perennis*), *Tephrosia Virginiana*, *Cassia Chamæcrista* and *C. nictitans*. Most of these are quite tenacious, and disappear only after several years of fighting against fate. The Composite family also contains a number of handsome plants, which cling to their old haunts persistently. *Asters* and *Golden-rods*, with *Chrysopsis Mariana* and *Diplopappus linariifolius*, are still found on the road-sides, and often in vineyards and orchards. Two Milk-weeds are common, *Asclepias tuberosa* and *A. obtusifolia*, the roots of which seem to be below the reach of an ordinary plow. For this reason great clumps of *A. tuberosa*, with its bright orange flowers, are often seen in vineyards and orchards which have been tilled for years.

But these native plants are, after all, only scattering individuals compared with the hordes of foreign weeds which follow man wherever he goes and begins to interfere with the native flora. Was ever a garden free from Purslane, even though planted in virgin soil? And the Pig-weed (*Chenopodium album*) soon follows, as well as the hateful *Amaranths* and *Shepherd's-purse* and the common prostrate *Mallows*. That most miserable of all pests, *Butter and Eggs* (*Linaria vulgaris*), came here among the earliest of the weeds. Some of the *Polygonums*, too, quickly gain a foothold, like the spreading *Door-weed* or *Knot-grass*, and the *Lady's-thumb* and the climbing *Bind-weed*. Others are later in making their appearance in our sandy soil. It was several years after the ground was cultivated before *Dandelions* were common. We had some difficulty at first in making them grow at all, but now they are everywhere on the road-sides, and they star every lawn with their bright flowers. For several years past I have made greater effort to grow *Catnip* than almost any other plant in my collection. I have several times planted seed, and have had strong roots sent from the north, but they soon disappear in spite of all my pains. The cats of the neighborhood are the cause of my failure. They are sure to break through any protection I can rear and gnaw the plants even below the surface of the soil. But the *Ground Ivy*, a near relative of the *Catnip*, has come to stay, for the cats let this alone.

For some fifteen or twenty years I never saw a *Mullein*

here, but now they are invading our ground in considerable numbers. I have not yet seen the *Burdock* nor the *Canada Thistle*, nor the *Hound's-tongue*, nor the *Beggar's-lice*—all vile weeds so common in waste-places and pastures of the north. Two species of *Buttercup* are just gaining a foothold, *Ranunculus acris* and *R. bulbosus*.

The common *Morning-glory* (*Ipomœa purpurea*) is a great pest in some vineyards and orchards, but how handsome the flowers are in the morning in their varying shades of color, from the deepest darkest purple and bright rose, with white throats, and beautiful shades of pink up to pure white. But the *Japan Honeysuckle* is worse than the *Morning-glory*. The soil suits it, and it runs rampant everywhere. It has escaped from cultivation, and is becoming at home along the country roads and in the edge of woodlands. It is an evergreen with us, and when kept within bounds is very desirable; but let the man who plants it buy a grubbing-hoe at the same time. The night-flowering *Catchfly* (*Silene noctiflora*) is another pretty weed that is becoming altogether too common in our cultivated grounds. The *Ox-eye Daisy* and *Mayweed* and *Yarrow* abound, of course, and were among the earliest of the weeds to reach us.

But one of the most remarkable of these foreign weeds is *Galium Mollugo*. It is only some twenty-five or twenty-six years since it was first observed growing spontaneously near New York City. It is a graceful, pretty plant, and, unlike our native *Galiums*, the stem is perfectly smooth. The small white flowers are in long panicles and quite fragrant. The leaves are mostly in whorls of eight; sometimes, when very thrifty, we find ten and twelve in a whorl. The sandy soil seems to suit it, and it grows most luxuriantly. I think, however, it will not prove very troublesome except in meadows and grass-lands. It flowers in May, when we sometimes see a meadow perfectly white with it, as if it had been planted for a special crop. It is also on the road-sides and along the railroad-tracks. Strangely enough, I am surrounded with it as I write, for it decorates my study-walls. Some designer of wall-paper has seized upon its graceful form and traced a pretty running pattern of this plant alone over a delicate buff ground. Unlike most designs of the kind, this one is very true to nature.

Vineland, N. J.

Mary Treat.

Mid-June in West Virginia.

JUNE is as much the *Honeysuckle* month as the month of *Roses*. The two bloom together in the poet's heart and should not be divided in the garden. If we had no other flowers in June this month would still be preëminent in delight-someness. Throughout the rest of the summer we shall have them with us, but not in their present lavish beauty. After the June blooming both *Roses* and the monthly *Honeysuckles* "bide a wee" to gather strength for a second effort.

As the *Roses* fade the golden-hearted *Lilies* open in the garden-borders and through the grass, while the *Hollyhocks*, in sturdy groups, stand ready to keep up the succession of showy bloom. This is the day of the late *Deutzias*. The double variety of *D. crenata* is now in full beauty; a graceful shrub six feet in height, blooming well on the upper branches, but more sparsely below. These shrubs are charming for grouping with deep red hybrid *Remontant Roses*, such as the *Giant of Battles*, *General Jacqueminot* and the *Baron de Bonstetten*. There is just now little bloom in the shrubberies. The *Purple Fringe* is preparing its rosy mist or "smoke," that will remain upon the trees for many weeks and form one of the most beautiful ornaments of the midsummer garden. These trees, or large shrubs, bloom when three feet in height, but are not in full beauty until they are about ten years old. They are apt to grow ill-shaped and straggling unless properly pruned when small.

Cotoneasters have now small inconspicuous flowers which are white and pink, and are eagerly sought by wasps and ants for the honey they secrete. The mature blossoms look like very small *Apple-buds*. They never expand fully, but have a little opening in the centre of each flower just large enough to permit the rifling of the honey within. *Itea Virginica* is very pretty now, with its numerous short racemes of tiny white flowers studding the bush and contrasting effectively with its light green oblong leaves. This shrub grows rapidly and spreads by many suckers, and is valuable for planting on the margin of large shrubberies. The curious, vase-shaped and coral-colored flowers of *Clematis coccinea* are now ornamenting the vine, which is, with us, of slender growth. It seems quite hardy, and is a pretty companion to a white *Clematis* which shares its trellis. Among the tall and showy *Pæonies* there are some striking varieties which rival the *Roses* in

beauty. Marie Stuart is very double, a fine satiny pink with a delightful perfume. Louis Van Houtte is purplish crimson, double, and effective in a mass of a dozen plants set at a distance of eighteen inches apart.

This is the season of most rapid growth in the vegetable world, and it is a keen pleasure to note how the frequent rains and warm, but not extremely hot, sunshine are bringing on our favorite shrubs and trees. A young tree which has been sent to me as *Cedrela Sinensis*, is making amazing progress, having shot up four feet since the expanding of its terminal bud in May. It looks very much like an *Ailanthus* to my uneducated eyes, but I am told that its large white blossoms are pleasantly fragrant.

One of the most interesting of the small trees in our shrubberies is *Parrotia Persica*. This has fine healthy foliage, which resembles that of the Witch Hazel, but is lighter in color and smaller in the size of leaves. The young growth is a pretty shade of pink. The tree is very ornamental, grows quite rapidly, and the foliage turns in the autumn to a fine dark crimson, lightened and shaded with orange and green. The blossoms come before the leaves, but our specimen has not yet flowered. The Witch Hazel itself, which is a near relative of *Parrotia*, is a very pretty and interesting tree, and is worthy of much more extensive planting than it receives.

Danske Dandridge.

Foreign Correspondence.

London Letter.

THE Royal Horticultural Society's great annual exhibition at the Temple has now become an important event in London. The progress of the society in popular as well as in professional favor is marked by the increased success of these exhibitions every year. An enormous crowd of people visited the show during the two days; even on the first day, when the price for admission was five shillings, the four large marquees and lawns were thronged with fashionable people, all more or less interested in the plants and in the society. If the Temple Garden is small, it has the great advantage of being central. The fact that the first day of the exhibition was the Queen's birthday, when all the law courts, etc., are closed, no doubt, had something to do with the exceptional number of visitors present on that day. As in previous years, the principal feature of the exhibition this year was the Orchids. Large collections of beautiful, rare, new and well-grown plants were contributed by the leading amateurs and nurserymen who are specially interested in Orchids. But while they were the first attraction, the collections of Ferns, Roses, hardy Azaleas, Begonias, Gloxinias, Clematis, herbaceous and alpine plants, stove foliage plants, etc., were of first-rate quality, such as would have made a grand exhibition had there been no Orchids at all. An enthusiastic and energetic executive, popular favor and glorious weather could scarcely fail in enabling the society to score a big success.

There is a great change in the character of these large plant exhibitions in London from what they used to be. Old stagers bewail the absence of this or that family of plants which once upon a time were favorites with exhibitors. But for my own part I like the modern exhibition, with its large collections of good interesting plants, represented by specimens such as any one can grow, far better than those huge elephant specimens which made everybody exclaim how wonderful, but really taught very little gardening. Here from Mr. May, of Tottenham, and Mr. Birkenhead, of Sale, were large collections of perfect little specimens of Ferns, such as one could carry home with him and keep in his own garden. Mr. Anthony Waterer's beautiful exhibit of hardy Azaleas was of the same character. You can take them and plant them in your border, and if your garden is not a brick-field they will be better yet next year. The same is true of the Orchids and other plants shown, no bedded-out specimens, no stiffly trained, wired, wadded, gummed, pampered-looking monsters, but good business-like plants, such as any gardener, let us hope, could grow.

Of course, there were plenty of novelties; far more, indeed, than I shall be able to mention. I will begin with the Orchids. The most beautiful specimen among these was a plant of *Cœlogyne Dayand*, from the gardens of Baron Schröder. It was in a basket a foot in diameter, and bore twelve pendulous racemes of flowers each a yard long. The Baron's collection was superb, both in interest and good cultivation. Splendidly flowered *Cymbidium Lowianum* (fourteen spikes), *Masdevallia Houtteana*, a large tuft of leaves surrounded by a broad ruff of flowers; *Odontoglossum Hallii*, var. *xanthodon*, *O. excellens* with a twenty-flowered spike, *O. crispum*, var. *apiatum*, a gorgeous variety, *Dendrobium nobile*, var. *nobilius*, *Vanda teres*, *Lælia purpurata*, *Ærides Savageanum*, a deep crimson-flowered variety, and the rare little *Dendrobium-like Hexisea bidentata*, which has numerous clusters of bright scarlet flowers as large as those of *D. Japonicum*. Sir Trevor Lawrence's collection was composed almost entirely of rarities and plants of exceptional interest. Among them were the new Sierra Leone *Polystachya bracteosa*, with broad flattened pseudo-bulbs and drooping scapes of brown and yellow hairy flowers; *Dendrobium lamellatum*, a remarkable little plant, with ancipitous pseudo-bulbs and white and yellow flowers; *Megaclini-ums*; *Masdevallia Mundyana* and *M. hieroglyphica*; *Sarcochilus Fitzgeraldii*; *Bulbophyllum Silemianum*, with yellow flowers, the lip crimson; *Cymbidium tigrinum*, *Cypripedium Philippinense*, *Dendrobium Brymerianum* and many more. Noteworthy among the other collections from amateurs were the following: *Grammatophyllum multiflorum*, with a scape five feet high and forty-six flowers, which suggested *Vanda Lowii*, being green-yellow with deep chestnut blotches. *Lælia majalis*, rarely seen in bloom, was here represented by a healthy plant bearing two magnificent flowers. *Brassias* of various kinds; *Odontoglossum Karwinskii*. *Lælia purpurata* variety, with the whole lip colored deep maroon; *Phalænopsis speciosa*, and many varieties of *Dendrobium Phalænopsis*. The most remarkable specimen Orchids were three huge plants of *D. nobile* from the gardens of Viscountess Postman. Each plant measured five feet in diameter and bore from a hundred to a hundred and fifty pseudo-bulbs all in flower except the immature ones, and each bearing from forty to fifty flowers. It was generally admitted that no such well-grown examples of *Dendrobiums* had ever been seen before.

Among the nurserymen, the collection of Messrs. F. Sander & Co. comprised a great number of beautiful and rare plants. *Cypripedium Chamberlainianum* was represented by eight plants in flower, only two flowers being open on each, the scape measuring about ten inches in length; the green and yellow sepals and petals and the peculiar shade of purple of the large pouch are quite different from any other cultivated *Cypripedium* known to me. A variety called *excellens* differs from the type in having a cream-colored dorsal sepal. *C. Vipani*, a hybrid between *C. niveum* and *C. lævigatum*, is a pretty plant, with white flowers streaked with crimson on the sepals and petals. *C. Exul* was shown under a glass case, a distinction it scarcely merited. *Oncidium Gravesianum*, a new Sanderian species allied to *O. prætextum*, *O. Rolfeanum*; *Cattleya Mossiæ*, var. *Arnoldiana*, white with purple shading on the front lobe of the lip, and yellow and brown-purple in the throat; *C. Schroderæ*, var. *virginalis*; *Odontoglossum excellens*, a beautiful variety; *O. Amesiæ*, a supposed natural hybrid between *O. crispum* and *O. Coradinei*; it has large well-formed flowers, white, with conspicuous blotches of chestnut-brown; *O. crispum*, var. *Wellsianum*, with large white flowers, the blotches of exceptional size, and the segments deeply lacinated; *O. crispum*, var. *Sanderianum*, with flowers as fine as those of Veitch's variety, but with more reddish brown. This is a wonderful plant, and an enormous price had been paid for it—higher than any ever yet paid for a single Orchid. *O. Lowryanum* has olive-brown flowers, with a little green, and a blotch of white on the labellum. *O. Pescatorei*, var. *Schröderæ*,

has creamy white flowers with a blotch of yellow at the base of the lip. *Cattleya Mendelli*, Cookson's variety, has very large flowers, with an exceptionally long, broad labellum and very richly colored. *Epidendrum Randii*, *E. Godseffianum* and a white-lipped variety of *Miltonia vexillaria*, called *Sanderiana*, were also noteworthy. *Masdevallia Measuresiana*, the interesting hybrid, and a still more interesting hybrid, namely, *Miltonia Bleui*, were also among Mr. Sander's many choice things. How comes it that a hybrid between two true *Miltonias*—namely, *M. Roezlii* and *M. vexillaria*—has been elevated to the rank of a new genus, and called *Miltoniopsis*? Mr. Sander had his plant labeled *Odontoglossum Bleui*, var. *splendidissimum*; it had large flowers, white, the petals rose-tinted, with radiating lines of red-brown on the labellum.

Messrs. Shuttleworth, Charlesworth & Co., of Bradford, exhibited many beautiful Orchids, including a grand lot of *Oncidium macranthum*, *Lælia purpurata*, *L. tenebrosa*, *Odontoglossum Wilkeanum nobilis*, a large-flowered variety with broad pale brown blotches and a tinge of yellow on the lip. *Cattleya intermedia alba*, the flowers absolutely white throughout, and a grand specimen of *Oncidium crispum* crowded with flowers. Messrs. B. S. Williams & Son contributed a large collection of well-grown specimens of *Vandas*, *Lælias*, *Miltonias*, *Oncidium concolor*, evergreen *Calanthes* and *Geodorum citrinum*. J. Cypher, of Cheltenham, famous for excellent cultivation of Orchids, sent a fine lot of *Cattleyas*, *Lælias*, *Cypripedium caudatum* and *Epidendrum radicans*, the last-named bearing eight bunches of bright orange-scarlet flowers. Messrs. Hugh Low & Co. sent *Cattleyas*, *Phalænopsis*, *Dendrobium superbum*, *Odontoglossums* and *Lælia grandis tenebrosa*.

The same firm contributed a beautiful group of *Ericas*, small plants well-flowered, their names being *Ventricosa grandiflora*, *V. Bothwelliana*, *V. superba*, *V. globosa alba*, *V. coccinea minor*, *Perspicua nana*, *P. erecta*, *Sindryana*, *candidissima*, *hybrida*, *depressa*. *Pimelia Hendersoni*, a dark-colored variety of *P. decussata*, attracted a good deal of attention, as also did a fine group of *Cytisus scoparius Andreanus*. This beautiful hardy shrub was also well shown by Mr. Anthony Waterer, of Knap Hill, who also sent a collection of his improved varieties of hardy *Azaleas*, including the double-flowered forms. It is scarcely necessary to recommend Mr. Waterer's *Azaleas* even to American horticulturists, as they are now as famous as his *Rhododendrons*. There was one, however, white-flowered, and called Mrs. A. Waterer, which shared with Baron Schröder's *Cœlogyne* the chief honors of the exhibition. Imagine a compact bush with ovate soft green foliage of good substance, and clothed with compact clusters of pure white flowers, with a pale blotch of yellow, the flowers as full as those of a good Indian *Azalea*. As a hardy plant this new seedling has a future of promise, and it looks very likely for forcing. Messrs. Laing's *Begonias* were magnificent, but they were not far in front of those sent by Mr. Cannell and Messrs. T. Ware & Son.

Messrs. J. Veitch & Sons had a large group of seedling *Streptocarpus*, another of *Gloxinias*, and another of the beautiful hybrid *Disa Veitchii*. In the largest tent the group of hardy plants from the same establishment was worthy of its reputation. It consisted chiefly of hardy *Azaleas*, *Hydrangeas*, *André's Genista*, *Spiræa astilboides*, *Azalæa amœna splendens*, a great improvement upon the type; *Cytisus scoparius pendula*, grafted on stems four feet high, and forming pretty little weeping specimens; *Ribes pumilum aureum*, a dwarf plant scarcely three inches high. Mr. William Paul's *Roses* were as fine as ever; so, too, were Turner's specimen *Pelargoniums*, and R. Smith & Sons' *Clematis*. A *Carnation* called *Almira*, from the gardens of Leopold de Rothschild, was worth special notice. It grows to a yard in height, and has large pale sulphur-yellow flowers with streaks of red.

Messrs. J. Backhouse & Sons, of York, sent a choice collection of hardy alpinæ, arranged in flat boxes with sand-

stone, so as to represent a miniature rockery. This exhibit was greatly admired.

Messrs. Linden, of L'Horticulture Internationale, Brussels, sent a collection of new stove foliage-plants, beautiful in themselves and beautifully grown. The beautiful yellow-flowered *Calla Elliottiana* was shown by its lucky possessor, who, we were told, had refused an offer of £500 for it. There is no doubt about its great beauty, flowers as large as those of the common white *Calla*, colored a rich citron-yellow, the leaves spotted with white. I am told that other people have, or soon hope to have, newly imported plants of this *Calla*. It is certain to become a general favorite. Mr. Rivers, of Sawbridgeworth, sent a grand collection of fruit-trees in pots, and bearing a good crop of ripe fruits.

London.

W. Watson.

New or Little-known Plants.

Cape Ivy (*Senecio macroglossus*).

THIS is a pretty yellow-flowered greenhouse-climber which deserves to be generally grown. It is rarely out of bloom at Kew, where it is trained against a rafter in the cool end of a large house devoted exclusively to succulent plants, a position which probably it has occupied for at least twenty years. Its shoots and leaves are very similar to common Ivy; indeed, I have been told that it narrowly escaped being destroyed for Ivy when it was first introduced. Planted in a well-drained border and not overwatered, it grows rapidly, draping in a year or so a rafter ten feet long with its elegant shoots. These are especially floriferous in winter and spring, the bright canary-yellow flowers almost sparkling in the sunshine. They are useful for cutting, lasting a week or so in water. Each head has usually eight ray-florets, with broad, elliptic spreading limbs, toothed at the apex. The disc-florets are also yellow. Sir Joseph Hooker says this is the largest-flowered species of the enormous genus to which it belongs, and which contains nearly one thousand species. It is a native of south Africa, from Algoa Bay to Natal, whence it appears to have been sent to Kew by Mr. Sanderson in 1868. It ripens seeds under cultivation, and it is easily multiplied from cuttings. In some parts of Italy and southern France *S. macroglossus* is not uncommon as a climber on verandas, and upon trees in the open air.

The German Ivy (*S. mikanioides*), which has thinner and larger leaves with smaller flowers, is grown as a window-plant in some parts of Germany.

W. Watson.

Cultural Department.

Notes on Shrubs.

LABURNUMS have this season produced a fine display of blossom in the vicinity of Boston. Like many other plants, they appear to have "off" years, when comparatively few blossoms are produced. I once had the impression that *Laburnums* should not be considered very hardy here, but after seeing their size and habit of growth in places near their native home, there seems good reason to believe that they ought to thrive here almost as well as they do there. In the vicinity of Boston and near the sea-coast there are specimens of *Laburnum vulgare* as strong, well-branched and shapely as could be desired. Yet the *Laburnum* is comparatively rare here, and this is probably due to several causes. It does not thrive if the situation is too wet, and in such places the stems are liable to be killed in winter. It will be found to do best in well-drained soil or on a comparatively dry bank. It is not a long-lived tree, its branches are easily broken, it seems liable to attack by borers, and destructive fungi soon get a foothold if the stem sustains any serious mechanical injury which tears the bark and exposes the wood. The *Laburnum* will grow and thrive fairly well in the partial shade of other larger trees or on the borders or edges of woods. In such situations it, of course, grows somewhat tall and spindling in habit, but grown as a single specimen, with plenty of light and air, it should become a compact, rounded little tree.

It is not commonly known that there are two species of *Laburnum* grown in gardens, and of these there are a number of

named varieties which have been selected and propagated by gardeners in the course of many years of cultivation. An examination of a large number of plants growing in various places in this region shows that with very rare exceptions they all belong to the so-called common Laburnum (*L. vulgare*), the species known as the Scotch Laburnum (*L. alpinum*) being very uncommon. The latter has smaller flowers of a deeper yellow color than those of *L. vulgare*; the standard usually has very faint marks or lines near the base on the inner side, and its lateral edges are often quite strongly reflexed. The flower-buds before opening are more flattened laterally. The leaves are glabrous on both surfaces, pale green beneath, and usually

Fig. 53.—*Senecio macroglossus*.—See page 294.

wider in proportion to the length, and the branchlets are smooth and shining.

In the common Laburnum the flowers are larger and lighter yellow-colored than those of the Scotch, the inner central lower portion of the standard is distinctly marked by dark red lines, and the lateral edges are not nearly so much reflexed. The flower-buds do not appear so much compressed laterally. The leaves are glabrous above, but grayish beneath on account of being covered by a minute closely appressed pubescence, and they are usually less than half as broad as long. The branchlets and winter-buds are grayish from being covered by a minute close pubescence. There is also a very marked difference in the fruit, the pods of the common Laburnum being thick-shelled and stout, while those of the

Scotch are thin and flat, the upper edge being prolonged, thin and knife-like. The seeds of both are said to be poisonous.

There are various forms of *L. vulgare*, of garden origin, which are often recommended as possessing qualities superior to the type. Of these probably the best variations are those known as Waterer's and Parkes'. There are also forms with abnormal foliage, such as yellow-leaved, curled-leaved, and with foliage so cut as to suggest diminutive Oak-leaves, but none of these are worth growing here except as curiosities or monstrosities.

A Laburnum both curious and interesting is that known as Laburnum Adami, famous as having been the result of a graft hybrid between the common Laburnum and *Cytisus purpureus*, a hardy dwarf, shrubby plant of the same family, bearing a profusion of purplish flowers at about the same season as Laburnum. This graft hybrid plant assumes the habit and stature of Laburnum, but its flowers may be purplish or like those of the typical Laburnum or those of *Cytisus*, and the foliage of either parent may appear in distinct branches and branchlets of the same tree, thus presenting a curious contrast.

Cytisus purpureus is well worth growing for its show of handsome purple bloom in the latter part of May and early June. It is a low, procumbent, spreading, slender-twigged shrub, scarcely rising over a foot above the ground, and on account of its inconspicuous habit European gardeners often graft it on tall stems of the Laburnum. But to many minds such treatment of it seems too artificial and out of harmony with the character of its foliage and blossom, and, besides, the plants do not thrive so well here, and are certainly not so sure of long life as when on their own roots.

C. nigricans, a later-flowering dwarf species, with slender spikes of bright yellow flowers, and several other kinds are often subjected to the same treatment of high grafting, but although they are rendered more conspicuous they are no more pleasant to look at than when growing in the natural way.

The Wild Garden.

THE sunny side of a large, abrupt mound, beside a pool of water, was absolutely covered with the beautiful flowers of *Phlox subulata*, the Moss Pink, during the month of May. It was a charming sight, and one that afforded a good illustration of the best place for this useful plant. The flowers are now almost past, except on the north side of the mound, where the plant is still very gay and makes an excellent associate for the fair Lily-of-the-valley. The reddish purple flowers of *Phlox procumbens* are also very showy, but this plant prefers a cooler situation.

Antennaria plantaginifolia, the Plantain-leaved Everlasting, covers a neighboring mound with its hoary foliage, and numerous aquatic plants luxuriate in the water beneath. A little tuft of Bluets occupies a quaint position on the root-stump of an Azalea by the watery margin, and Marsh Marigolds are still a beautiful spectacle of orange-yellow flowers and verdant foliage in the rich mud adjoining. The pretty racemes of the Buckbean, *Menyanthes trifoliata*, peep above the shallow water a little further along, and the yellow Pond Lily is showing its large, golden balls in the deepest places. On an adjacent, shady bank, *Geranium maculatum* thrives beautifully, and its pale, purple flowers are prettier than those of many a more costly plant.

Ferns and *Aquilegia Canadensis* make a most effective combination among the rocks and earth, forming an irregular mass, the rich red and yellow flowers of the Columbine having an exquisite setting in the varied shades produced by the Fernfronds. The white flowers of *Anemone Pennsylvanica* have unfolded. The plant is a robust grower and blooms freely. It thrives best in a dry, open position. The flowers are two inches in diameter, with a pretty cluster of yellow stamens in the centre, and they are produced most abundantly where the plants receive the greatest amount of sunshine. *Clematis ochroleuca* is interesting on account of its rarity. It is about two feet high, and blooms freely in the sun. The urn-shaped flowers are purplish outside, creamy within, and they are borne singly at the top of the stems.

The Wild Hyacinth, *Camassia (Scilla) Fraseri*, is strikingly handsome. It has long, linear leaves and scapes more than two feet high. The flowers are pale blue, an inch across, on pedicels an inch long, and arranged closely on the upper portion of the scape, covering about a foot of its length. Unlike *C. esculenta*, it is perfectly hardy in this latitude, and it flowers freely during May and June. It needs a deep rich soil, and plenty of light is beneficial, though the flowers fade rapidly if they are not sheltered somewhat from the sun. This is undoubtedly

one of the best native bulbous plants for garden cultivation, and one that should be in every collection, however small.

The Mossy Stone Crop, *Sedum acre*, is ablaze with its golden flowers, and it is one of the most useful things for those dry or rocky situations in which dwarf plants are required. It makes a delightful natural edging for a portion of the wild garden, and it would be no less effective or desirable for similar purposes in gardens of greater pretensions. Moneywort, *Lysimachia nummularia*, and the Field Chickweed, *Cerastium arvense*, are useful in the same way. The former is not yet in bloom, but its thick carpet of fresh green leaves is worth a great deal, and the little yellow blossoms will appear in due season a few weeks hence. *Cerastium arvense* is also close and compact in growth, and its leaves are small and pointed. It is in full bloom now, a mass of snowy whiteness.

Rich groups of color are supplied by *Thaspium aureum*, *Amsonia Taberæmontana* and *Baptisia australis*, the Blue False Indigo. These plants are from three to four feet high, and require good deep soil and full exposure to sunshine. They are most effective in large masses, but make beautiful and shapely clumps of a size suitable for mixed borders. They all bloom freely. The flowers are small in the *Thaspium*, of orange-yellow color, and are borne in dense umbels from two to three inches across. In *Amsonia* they are of a light blue color, an inch across, and produced in large terminal panicles. The *Baptisia* has large Pea-shaped flowers, of pale blue color, in long, erect racemes.

Erigeron bellidifolius forms a thick, dwarf undergrowth, and sends up straight, sparsely leaved stems to a height of eighteen inches, each bearing from six to eight Daisy-like flowers, an inch and a half in diameter, with yellow disk and lilac ray florets. It is an admirable plant for a sunny situation. *E. flagellare* is a pretty dwarf species of creeping habit. The stems do not exceed six inches in height, and the whitish flowers are somewhat smaller than those of *E. bellidifolius*. The compact clusters of *Thermopsis mollis*, about two feet high, have a pleasing effect. The long terminal racemes of clear yellow papilionaceous flowers are very showy and useful at this time. Its taller-growing relative, *T. Caroliniana*, blooms a month later. Both plants flower freely, and grow well in ordinary garden-soil.

One of the best wild flowers for shady places is the False Spikenard, *Smilacina racemosa*. It is about four feet high, and the simple stems are furnished with large green leaves. The flowers are cream-colored, fragrant and small, but they are produced in immense terminal racemes. *Polygonatum giganteum*, the Great Solomon's Seal, also grows luxuriantly and flowers abundantly under trees, and so does *Arisæma triphyllum*. The spathes of the latter plant, however, develop their pretty colors much better under the influence of winter.

Cambridge, Mass.

M. Barker.

Flower Notes.

IT is a good time, as the flowers of certain plants pass away, to destroy those which for any reason are not desirable. By prompt action of this kind, while the dissatisfaction still lingers, one parts with the plants without regret, and the general effect of the garden is improved. We are apt to delay this often important weeding-out so that undesirable plants are grown year after year. To a special collector any variety of a given family of plants may prove interesting, but to others there is no family in which the average grower will not find some practically worthless members. The grower who simply cares for attractive plants will discard those which have a merely botanical interest, which are unsuitable for available positions, or whose form or color is displeasing.

It is interesting to study any family of plants and separate them into classes. As a practical example take the Columbines, which happen to be plants, some of which are still in bloom. Looking over a collection of them in flower the most striking difference will be found in the varieties considered as effective or showy garden-plants. It is no fanciful division to separate them into three sections, of which the long-spurred, bright-colored ones, like *Aquilegia chrysantha*, *A. cœrulea* and *A. truncata*, may be considered the vivacious members. Varieties of *A. glandulosa*, *A. grandiflora alba*, *A. Pyrenaica* are quiet and reposeful, while many of the short-spurred, dull-colored kinds are vapid and spiritless in effect. It is curious to note that the vivacity of a flower depends more on the combination of form with color than on color alone. This may be seen by comparing flowers of the same color, but with dissimilar forms. As a bright, effective, vivacious flower *A. chrysantha* is not surpassed by anything in the garden, a golden flower, poised delicately in air as if in flight upward.

The due consideration of the different effect of these plants will cause them to be placed by the careful gardener in positions where these qualities may be most effective. Most of the Columbines are plants for the less conspicuous parts of the garden, but if planted in prominent places such kinds as *Munstead White*, for instance, are more suitable than *A. Canadensis*, not because this is not equally beautiful, but because we naturally associate our favorite wild Columbine with woods and rocks and informality.

The various notes on *Narcissi* also remind me that in this family also may be found varieties which are not effective as garden-plants, though I know of no variety which may be considered altogether vapid. The most surprising thing, considering the vast numbers of *Narcissi* now in cultivation, is that the varieties are really distinct, though often slightly so. The distinctions are often only clearly seen, however, when the plants are grown in masses. There is, no doubt, often much disappointment felt on the first view of many Daffodils, and especially over the pallid kinds, the pale yellows, the pale sulphur and alleged creamy whites. Even in masses these cannot be considered effective garden-flowers, but they are valuable under artificial light and make excellent flowers for the house. Of course, such useful plants can be grown in inconspicuous positions. On the whole, yellow flowers are the most attractive of any color for the garden, but there is a vast variety and choice in yellow. The tones seem infinite, and probably indescribable without examples for illustration. The largest number of Daffodils are yellow, and the principal dealer's list uses a score of designations, from pale primrose to deep golden, in the endeavor to describe the different tints. Considering that the tones vary somewhat with the different seasons and the soil of different gardens these fine distinctions are not very helpful. If the beginner asks for help in all this confusion of names and tones, probably the best advice would be to commence mostly with the large trumpets, avoiding the pale primrose and light straw-colored sorts on the one hand, and the very deep yellow ones on the other, as described in a reliable list.

J. N. Gerard.

Hardy Plant Notes.

THE hardy perennial borders are now in their best condition, since the season, though late, has been favorable for all plants of this description, and none have been injured by late frosts, as is often the case. The Oriental Poppies are now in their glory, and force all other flowers in the background with their strong color. The true *Papaver bracteatum*, though considered a form of *P. orientale*, is by far the best Poppy grown as to color. Carefully selected seeds of *P. bracteatum* will not come true, but will revert to the common *P. orientale*, so that it is necessary to propagate it from root-cuttings. Pieces of root an inch long are a suitable size. If taken when the plants die down soon after midsummer, these should be dibbled into sand to start them and may be planted out in fall or wintered over in a cold frame, and they should flower the next season. A variety obtained in seed as *P. bracteatum præcox* is no earlier and differs in no way from the common *P. orientale*, though we had hoped better of it. The variety sent out some time ago as *P. Parkmanni* does not seem to be any different from an ordinary Oriental Poppy, though distributed at a high price and with a great flourish. It is well to remark that Oriental Poppies vary more than is supposed from seed, and it is difficult to find any two that are exactly alike, both in color and in the markings at the base of the petals.

Lindelofia spectabilis præcox, we are told, is often sold in Europe for *Mertensia Virginica*, our beautiful native Lungwort, though it is difficult to understand why, as the plant has nothing in common with *Mertensia* except that it belongs to the same order, *Boraginaceæ*. The *Lindelofia* is perfectly hardy, though a native of Kashmir, and bears a quantity of bright blue flowers for several weeks at this season. Seeds are very slow to germinate, often taking several months, and they always come unevenly. This is a monotypic genus, and the flowers of *L. spectabilis* are said to be purple-red, a very different combination from that of our plants, which are of a real Gentian blue. Flowers of a different color, even on the same stem, are common in this family, as in the *Borage*, *Mertensia*, and in a plant now in bloom called *Caccinia strigosa*. This plant is a native of Afghanistan, and has wintered out safely; its chief beauty, however, lies in its foliage, which is of a decided glaucous or grayish color, and at once arrests attention in a border of mixed plants. In this plant different flowers are both pink and blue at the same time. Our plant is

not strong, but in time may improve and gain vigor, since it is now flowering for the first time from seed.

Iris Troyana belongs to the rhizomatous section of Iris, with such varieties as the German Iris, and is quite distinct in color from most of these, though of the same habit and time of flowering. I cannot find any account of the species published, and am at a loss to know more of the plant, as it is hardy, and is in bloom in eighteen months from seed, quite an unusual occurrence for an Iris.

I wrote of *Lathyrus tuberosus* last year as a very pretty hardy tuberous-rooted Pea, all of which is true, and it is equally true that this Pea, like *Apios tuberosa*, has the remarkable ability for coming up in all places but the one in which it is planted. Though the plant is exceedingly pretty when in bloom, it is not fit for a flower-border, as it spreads too rapidly and takes hold of other plants and chokes out. But if planted where it could be left to its own way of growing, as in a wild-garden, it would be a thing of beauty many weeks.

Adlumia cirrhosa, or Climbing Fumitory, is a graceful twining plant in the second year of its growing, with small inconspicuous flowers of very little value, but we find the plant of much use when raised in spring and planted out where it will quickly form a dense mass of most elegantly cut leaves, which makes a good substitute for Maiden Hair Fern with cut flowers, and lasts much longer. We used these leaves all last summer, and saved the Fern for winter use. The second year the *Adlumia* loses all its tufted habit and throws up tall stems that need support, as it is a true climber. Unlike most of this family, the *Adlumia* is readily obtained from seed sown early in spring. Another of the Fumitory family recently noted in these pages is *Corydalis nobilis*, a truly noble border-plant when well grown, but very seldom seen in gardens. It needs to be left alone when once planted, as the roots have the appearance of being half-decayed. These are easily obtained in fall from Holland with the Dutch bulbs. *C. nobilis* is the finest of the genus, and well deserves to be much better known.

South Lancaster, Mass.

E. O. Orpet.

Iris cuprea.—Of the species of Iris now in flower this is one of the most distinct and attractive. The leaves are sword-shaped, slightly lax, and grow to a height of about eighteen inches in a dry position. The flowers are rather numerous, and of a peculiar dull copper-color, quite distinct from any others in the same family. The standards and falls are broad, and in some stages form a flat flower somewhat in the style of *I. Kæmpferi*. A native of the southern states, this plant probably requires a rather warm place. It proves a thrifty plant in such a position.

Iris ochroleuca, or *I. gigantea*.—This may be recommended where a noble tall-growing variety is desired. The leaves are deep green and about three feet tall, above which the long stems carry the clustered white, slightly mauve-tinted flowers with orange markings.

Iris Anglica, in the same border, makes a perfect succession to the Spanish Irises, whose flowers have passed before the middle of the month. Both sections of these bulbous Irises are desirable and popular garden-plants, but require care in the selection of a suitable position. They evidently need a dry hot place, where the bulbs will roast while resting. The Spanish Iris throws up its leaves in early winter, and sometimes there are complaints that these are injured in hard weather. Mine, planted under the lee of the house, have never so suffered, and prove reliable plants. Their flowers are quaint beauties, showing great variety, though not as large as the English Irises, neither are the plants so vigorous. Of the English varieties the white variety, *Mont Blanc*, is a well-known kind, very beautiful and desirable for a special clump.

The Forest.

The Woods of Minnesota.

IN the nineteenth Annual Report of the Geological Survey of Minnesota, the State Geologist, Professor N. H. Winchell, has devoted a chapter to the forests of that state, and has entrusted its preparation to Mr. H. B. Ayres, then agent of the Forestry Division at Washington. In his general description of the forests of the state Mr. Ayres separates them into groups, the most important of which is the White Pine region, varied with hardwood, Norway and Jack Pine, Cedar and Tamarack swamps, with open or Spruce bogs bordering the numerous lakes or occupying

their old beds. This region is so well watered and has so little fall that very little of the White Pine is more than five miles from streams through which it can be driven. Nearly all of the streams head in the open bogs, which, where partly shaded by Spruce, make an enormous growth of sponge-like Sphagnum-moss, and this holds the ice of winter until June or July, and preserves a supply of water, so that the explorer may find it under some upturned root well into the droughts of August and September. The soil is usually loam or clay, and supports a considerable growth of hardwood, among which the White Pine reaches its most perfect development. To give some idea of the recent history and the prospects of this region we quote directly from Mr. Ayres' paper:

Much of this whole area was stripped by fire even before the loggers increased the liability to fire by the tops they leave in the woods, and by the greater drying of the forest-floor by exposure to the sun and wind in the openings they have made. It has been estimated that thirty years ago over 40,000,000,000 feet of Pine were standing on the 25,000,000 acres of forest in the state. Since that time busy milling-towns have started up here and there as if by magic, and loggers and choppers have swarmed into the forest until the average number of men now employed in preparing forest-products for market reaches about 17,000, and the value of the product as placed upon the market amounts to about \$31,635,000.

Must the industry soon decline? The answer is a prompt and positive No.

If timber were a deposit like beds of iron-ore, with no power to reproduce itself, we could readily estimate the time of the end. In such a case we could see that, with the present supply of standing timber, say 20,000,000,000 feet, seventeen years more would leave the state stripped. But where fire is kept out forests reproduce themselves, and the accretion by growth, while small and of comparatively little value in woods cut without any view to reproduction, in woods cut at such a time and in such a manner as to give the seedlings and sprouts the best chance to make a rapid "second growth," the annual increment under the best forest-management in Europe has averaged about fifty-five cubic feet per acre, one-third of which should be estimated as log-timber. To produce an annual growth of 1,200,000,000 feet B. M. (the latest annual cut) would at this rate require 5,500,000 acres.

In mournful contrast with these results obtained in Prussia, stands the estimate, though roughly made and presented with some hesitancy, yet approximating the fact, that the 24,960,000 acres of wooded area in the state did not last year grow more than 200,000,000 feet B. M. of log-timber. In other words, 50,000,000 acres of such forest as ours in its present condition would be required to grow the amount grown on 5,500,000 acres of well-managed forest, and our forests are thus only producing less than one-ninth of what they might. We must not, however, forget that of the 24,960,000 acres now wooded, probably one-half will eventually prove more valuable as agricultural than as forest land, and should be partly cleared. This would leave the area that should always be kept in forest—that is, the lands unprofitable for agriculture as compared with forestry, about 12,500,000 acres, which should, under management, produce twice our present annual cut of log-timber, and 400,000,000 cubic feet of other material for wood-working, fuel, etc.

Every considerable tract of forest in the state is more or less depleted by fire, and can only be brought into full production after many years of renovation; but should any reader be tempted to cast these estimates aside as overdrawn, I must ask him not to do so without a careful study of the subject, such as I have given it during four years of exploring that have taken me all through the wooded region and formed in me a deep conviction that, while these estimates are necessarily rough, they are based on sound principles, and at least point toward and approximate the truth.

Theoretically, therefore, it seems possible that the present yield of log-timber alone may be doubled permanently and that a vast increase of manufacturing industries would follow the assurance of a constant supply, and, locating themselves throughout the woods, would in every way tend toward the greatest development of the state. Practically, however, the difficulties in the way of attaining this ideal state of affairs are so great as to try the determination and skill of our best citizens.

The difficulties attending the question of ownership before operations of any kind can be commenced are the greatest that are to be met in the whole subject. In Europe, however,

where claims of private owners were everywhere to be adjusted before anything could be done, this great barrier has been overcome satisfactorily to all. In this country, where so much of the lower grade of agricultural land is owned by the government, there should be great hesitancy in making a beginning, beyond the caution necessary to make sure that the course be the right one. In Europe the great difficulty has been just as here, the prejudice against anything but the free use of public property and against interference of the government in the business of individuals. But they have, first in the mountains where the general welfare most plainly demanded it, by condemnatory proceedings, and later, on the poorest lowlands, where the direct profits of forestry are greater than those of agriculture, by bounties to the owners of the land, made such progress during the past century that the wisdom of the movement is plainly shown, and all men who have the chance to know, combined with a desire for the public good, write in sustaining the governmental policy of securing the perpetual cultivation of forests on all the poorest lands.

Correspondence.

Impressions of America.—I.

To the Editor of GARDEN AND FOREST:

Sir,—My first impressions of America were received in the beautiful fall of the year. I came to Boston on a Monday, early in October, after a morning sail up the harbor where the dark brown summer hotels and cottages, encircled by broad piazza roofs, looked to my astonished eyes like gigantic fungi planted in the bare grass. After a dazed and lonesome day in Boston and bewildering experiences with imposing darkies and strange things to eat at a solemn hotel, I was taken out to Wellesley Hills by a kind friend, and thus introduced to a suburban town while everything was quite new to me. Our voyage had been a long and a stormy one and had left my mind as complete a blank as any traveler could desire. All was, indeed, so new to me that it made no impression at all, beyond a vague general one of great and wonderful strangeness. Some things there were to remind me of my own country, Sweden, while I caught occasional glimpses that recalled France. From among features of house and landscape, something would flash across my vision that had no association with anything at all that I had ever seen or pictured in fancy. Supper brought sword-fish—an animal connected in my mind with museums and picture-books, not with the dinner-table; a curious vegetable, fit food for the gods in its rich color and aromatic, poetically suggestive flavor, which they called sweet-potato; an outlandish, highly spiced tea, which they called Oolong; a variety of light tempting breads and delicious stewed fruit, all served up at once in home-like abundance and suggestive of a land of new products and boundless resources.

Next morning I started on a walk through the village, full of eager curiosity, unaccompanied, as I wished to receive unbiased impressions. It was all very strange, utterly unlike everything I had seen before of any known or tried principle of arranging human dwellings. On either side of a splendid avenue, too broad and lofty to be oppressive, arching more grandly and lightly than most avenues in Europe, little houses, as contorted and fantastic as if they represented wants and tastes quite different from ours, were set in rows in the grass. Each house had a straight little path leading up to the front door, creepers trailing over the piazza, a few fruit-trees or a row of evergreens in the grass in front of it, but not a sign of a hedge or a fence visible anywhere. Flowers, too, were rare, but vistas of sunny plain showed in the open spaces between the houses, and in the morning light it all looked so new to me, so broad and open and suffused with light, that I suddenly felt as if I had climbed the Bean-stalk in the night and was wandering about dazed in a new and strange world, of bright light, quaint customs, and unbounded friendliness and good-fellowship of intercourse.

My walks in the woods, alone or with friends, were full of delightful experiences, very bewildering at first when I encountered Blackberries that grew on trailing vines instead of on stiff tough brambles, as they do in Europe, or Maples with leaves so deeply indented that they look like Oaks, while the most prevalent Oaks, with their regular build, their burnished foliage and the clearly cut symmetrical form of their leaves, almost like a conventionalized Acanthus, did not at all answer to my English ideas of an Oak. The Elms were graceful, spreading things, not the heavy clumps of massed foliage that I was accustomed to in England and elsewhere. In between these

new forms and manifestations were well-known European trees or features of landscape, low picturesque stone walls, that I thought impossible out of stony treeless western Sweden, running along below huge Chestnuts, like those I had seen last in the mountains above the Italian lakes; hill-formations and road-side ponds or bits of Oak and undergrowth so characteristically French that it was like seeing a succession of landscapes by Daubigny, Cazin and Rousseau. Add to this the sight of the White Pine, that pride of our evergreen shrubberies, growing wild; Sycamores and Plane-trees, with foliage either much more magnificently grand or much more minutely delicate than in average central European specimens; sylvan forms on the grandest scale in endless variety; long threads and tangles of Virginia Creeper thrown up among the branches of the old trees like Lianas in pictures of the tropics; or something still more suggestive of the tropics, a beautiful vine, now turning deep red, which I was warned against as poisonous; stray flowers of refined beauty in the ditches, and the clearings full of a feathery shrub; the Sumach, interspersed with a tall exquisite plant, the Milk-weed, eminently Japanese in its pale green color and the quaint pear-shape of its large pods; more old friends in new places and unexpected glimpses into a picture-book world, until it all seemed to me like the title-page of some old illustrated book of geography, on which plants and trees from the different countries are arranged in picturesque confusion.

Besides the combination of opposites, the prevailing impression was one of luxuriant profusion. I remember passing through an orchard and being told to pick up a sweet apple which fell at my feet, a thing I would not have dreamed of doing in an orchard belonging to strangers in Europe. A sweet apple in Sweden has a flat, insipid taste, but this had a rich lusciousness of flavor and an abundance of juice that seemed to me truly to symbolize America.

Underlying all this there was something disappointing and inconsistent that disturbed me, though I could not explain it to myself. I can explain it now only too well, and as the explanation is my sole excuse for setting forth all these personal impressions I shall give it here. I know, now, that I was disturbed by the inconsistency between the luxuriousness of the woods and the barrenness of the gardens. In our daily life I did not notice it much. The piazza, with its translucent screen of vines, the still sunny air over the Apple-trees and the grass, were very pleasant after my voyage, and the sociability existing between the different houses in this Jack-o'-the-Beanstalk land was very quaint and amusing. But every walk in the woods made the bare front yards I passed on my way home seem more and more astonishing and finally painful to me.

Since then the well-known fascinating power of America has been at work, and I have learned to look upon her more as a country which I have a right to be interested in and to criticise from the standpoint of my sympathy and admiration than as a foreign land to be observed with cold and dispassionate curiosity. Further acquaintance with suburban districts and gardens has only served to deepen and give clearness to my first impressions. New England seems the land of boundless resources, of unlimited possibilities of beauty within the fine art of gardening. But the fine art of gardening is as yet only a luxury of the wealthy.

Milton, Mass.

Cealia Waern.

The Wellesley Gardens.

To the Editor of GARDEN AND FOREST:

Sir,—The gardens at the country home of Mr. H. H. Hunnewell, at Wellesley, Massachusetts, are certainly unique, and rank among the very best examples of modern horticulture in the United States. In extent and completeness they resemble the spacious old gardens of Europe more closely than most others in America, and the forms of gardening carried out are so numerous and well maintained that the place has hardly a superior anywhere. The natural features of the place have been carefully studied, its beauties emphasized, and its less interesting portions relieved by plantations in which the trees are artistically grouped, or arranged in vistas which carry the eye to where distant woods and skies unite upon the horizon-line. The house itself is situated on something of an eminence, overlooking the picturesque Lake Waban, whose shores exhibit beautiful lines with jutting bluffs, and sweeping inlets, and they are finely wooded on all sides. The buildings of Wellesley College rise grandly on the right, their classic designs and lively colors imparting brightness and a certain oriental luxury to the scene. The place, too, has taken on

much of the dignity which comes with age—a too rare feature of American gardens.

The most experienced gardener may learn much at Wellesley, and he can find many object-lessons there at any time. The attractions of the place are particularly numerous and varied at present. The "Italian Garden" (see GARDEN AND FOREST, vol. ii., p. 103), so-called, is worth a journey from any part of the United States, to those who have never seen anything of the kind. It occupies the sloping ground between the house and the lake, and consists of a series of terraces on which trees and hedges of various kinds, clipped to formal patterns, are growing. This kind of ornamental gardening originated with the Dutch at an early period, and was copied in later times, with some modifications, by the horticulturists of several other European countries. There are only a few of these gardens now in existence, and that at Wellesley is the only one of any considerable extent in this country.

The plants at Wellesley are in many cases not the same as those employed in European examples of topiary work. The Hemlock, Beech (both the purple and green forms), Norway Spruce, White Pine, Scotch Fir and Arbor Vitæ are the most plentiful. A low wall on one of the back walks is decorated with tall, columnar specimens of Juniper and Irish Yew, arranged on the flat top in the form of a colonnade. These two latter plants are grown in tubs for greater convenience in storing, since they are not hardy here.

Glimpses of a large white tent in another part of the grounds now strike the eye through the shrubbery, and on investigation it is found filled with handsome specimens of greenhouse Azaleas. The pots are plunged to the rim in the sod, and the plants are so well arranged that they seem to be in permanent position. There is no sheeting to the sides of the tent, but there is a large plantation of hardy Azaleas on the outside, and the soft colors of their flowers form a charming background to the brighter blooms within. Several large trees, beautifully draped with white and purple Wistarias, are also noticeable in close proximity, and Mr. Harris, the gardener, called attention to some specimens of a very good new Japanese Azalea, which had proved perfectly hardy at Wellesley last winter. This is certainly an acquisition as a hardy plant, the flowers being large, handsome, and of a rich purple shade.

The simple, daisy-like flowers of the Marguerite (*Chrysanthemum frutescens*) were very attractive on large specimens around the base of the central tent-pole. This is an admirable decorative plant, as easy to grow as a weed, though it will not stand frosts, and it may be made useful in a thousand ways.

The Rhododendrons are a striking feature of the place, and they are to be found in large groups on every side. They bloom during the early weeks of June, and their magnificent trusses of flowers are then distinguishable miles away. The plants like a peaty soil that is moist and cool, and a thorough mulching of litter tends to preserve these conditions in very hot weather. Mr. Harris assured me that it has been amply demonstrated by experiment that the most important varieties of Rhododendrons require no protection in winter at Wellesley. This is encouraging for those who wish to grow these most desirable shrubs, for the climate of Wellesley is by no means mild. The statement of Mr. Harris is doubtless true as regards immediate protection, but in no case, as far as I could see, are the plants wholly unsheltered on dangerous sides. The position of the plant is often its protection, and the trees and hedges adjacent to the Wellesley plantations of Rhododendrons go far to preserve them from destructive winds and sunshine.

The Rhododendron beds are edged with variegated Funkias, and there are many splendid specimens of rare conifers about the grounds. Limited time allowed me only a glance at the interesting rockery convenient to the Italian Garden, but I noted the variegated form of *Evonymus radicans*, almost rivaling *E. latifolius variegatus* in the proportions and excellent color of its leaves, and the large bushes of *Kalmia latifolia* in bud, promising a rich display of bloom a few days later.

Some Peach-trees and Grape-vines in the fruit-houses gave every indication of heavy crops, and the numerous structures devoted to stove and greenhouse plants were amply stocked with general material, and gave evidence of high cultivation. A large area of glass is taken up with choice Orchids. These plants especially are all in the most vigorous health, and many of them are flowering profusely. Their excellent condition is largely due, without a doubt, to the rich liquid manure which is freely applied to their roots. The conservatory adjoining the dwelling-house contains a fine collection of Orchids in bloom. The plants, even the best of them, are far too numerous to specify, and they produce an effect which in itself is worth a journey of many miles. I cannot refrain,

however, from mentioning *Dendrobium Wardianum*, which was represented by a large number of specimens, conspicuous for their superb condition at a period of the year so far advanced. A grand plant of *Medinilla magnifica* occupied a prominent position in the same house. The temporary awning directly outside covered well-grown *Achimenes*, *Gloxinias*, *Imantophyllums*, *Calceolarias*, *Pelargoniums*, *Fox-gloves* (first-class in pots), *Spiræa Japonica grandiflora*, *Wistarias*, *Eurya latifolia* and *Rhynchospermum jasminoides*.

It has taken over forty years of persistent and intelligent care, with a great outlay of money, to make the gardens of Wellesley what they are to-day, and in view of this it would appear ungracious to close this notice without an allusion to the public spirit and generosity of Mr. Hunnewell in throwing all these horticultural treasures so freely open to the public.

Albinos among Orchids.

To the Editor of GARDEN AND FOREST:

Sir,—In your issue of March 23d J. T. describes the finding of a white-flowered plant of *Habenaria psycodes*, and asks if any one else has ever found one.

On the 30th of last July I collected what I judge to be the same variety, along a damp road-side a few miles from North Anson Village, Maine. The white variety was almost as abundant as the type, with which it grew. The specimens were new to me, but on account of their number were supposed, at the time, to be some ordinary white-flowered *Habenaria* common to the region. They were placed in the vasculum without even a thought as to what species they might be. On account of their beauty a handful of the spikes, both white and purple, was collected as a bouquet, and a very pretty one they made.

Upon returning to the village it required but a moment's examination to identify the flowers, the variation from the type being very slight, except in the pure white of the flowers and the less deeply fringed lips. Although the white-flowered plants were not examined critically or compared with the common variety at the time of collecting, the impression received from subsequent observation is that the white form is an albino, and not a hybrid, as was suggested to your Norwich correspondent. The flowers discolor in drying as quickly as do those of some other allied species.

Preference of Birds for Certain Trees.

To the Editor of GARDEN AND FOREST:

Sir,—I quote the following passage from a recent number of the *Mediterranean Naturalist*:

"It is remarkable that no writer has noticed the preference that certain species of birds give to certain trees. Jays and rooks are found in the greatest numbers in Oak-trees, finches in Lime-trees, and black-caps among the Laurels. The nightingale is always found in the greatest numbers in nut-groves, while the thrush evinces a decided preference for the Birch and Ash. The Beech is the favorite tree of the woodpecker, and the numerous families of tits are generally found in the greatest abundance among the Black Thorns."

I am not familiar enough with birds, or with books about birds, to know whether this writer is, indeed, the first to call attention to such preferences. Perhaps some of your readers can say whether they have been observed by American naturalists, and, if so, whether the American relatives of the birds here mentioned are akin to them in their tastes.

Trenton, N. J.

The Effects of the Winter.

To the Editor of GARDEN AND FOREST:

Sir,—Judging from recent correspondence in your journal, the past winter has had unusual effects upon trees and shrubs in New England. It is certainly so with us. Here, in the Atlantic provinces of Canada, we had very little snow in early winter, and a late and dry spring. I expected to find grass-fields suffering from the exposure, but cannot see now that such is the case to any unusual extent. In this town, however, and in the immediate neighborhood, Raspberries of the hardiest varieties have been winter-killed so badly that not one cane in a hundred will show a blossom; while hardy Roses, usually killed back for one-third or one-half their length, are coming out better than I have ever seen them in some twenty years of observation. The only other remarkable thing noticed

is that we have lost all the Trumpet Narcissus, usually very hardy here, while the double form of *N. poeticus* is better than usual.

St. Stephen, N. B.

J. Vroom.

Notes.

We have received a few flowers from Rea Brothers which are labeled *Achillea Mongolica*. They are long-stemmed, white semi-double flowers which are said to bloom earlier than either *A. ptarmica* or *A. serrata*.

The delicate and fragrant flowers of *Clematis crispa* have been opening for a week, and they will continue to appear every day until the time of heavy frosts. This is one of the climbers which can be recommended for every garden.

Robinia Neo-Mexicana is flowering this year in the Arnold Arboretum, probably for the first time in cultivation in America. It is a small tree, a native of the southern Rocky Mountain region, and the only representative of the genus in western America.

Mr. James MacPherson writes from Trenton, New Jersey, to the *American Florist*, that a bulb of the variety *Superbum* of *Lilium Wallichianum*, planted out last year on a steep bank and covered with a little litter, has survived the winter and is now growing strongly.

In speaking of the readiness of the various Columbines to vary and hybridize, Mr. T. D. Hatfield writes of a giant form of *Aquilegia Canadensis* which has the perfect flower of the type but shows in a striking way the habit of *A. vulgaris*. This plant is usually three feet in height.

The second instalment of Professor Coulter's *Manual of the Plants of Western Texas*, embracing the Gamopetalæ, has appeared, forming Number 2 of the second volume of the *Contributions from the United States National Herbarium*, published by the authority of the Secretary of Agriculture.

Dr. H. T. Bahnson, of Salem, North Carolina, sends us flowers of a new seedling *Nymphæa*. They belong to the same type as those of *N. alba*, a light shade of pure pink in color, with petals numerous and very broad. The flowers are bold, as large as those of *N. alba candidissima*, and quite distinct. The new variety is evidently a desirable one.

By ministerial decree a committee, consisting of Comte de Choiseul, President; Edward André, Vice-President, and Henri L. de Vilmorin, Secretary, has been appointed by the French Government to represent French horticulture at the Chicago Columbian Exposition, and Monsieur André has been entrusted with the duty of preparing the plans for the garden of the French section of the exhibition.

Professor Penhallow writes to the *American Geologist* of two specimens of fossil wood which were recently exhumed from different places in Manitoba. Microscopical examination shows that they are identical and that they possess characters approaching both *Larix occidentalis* and *L. Americana*, but are, in other respects, quite distinct from both. The specific name, *L. Churchbridgensis*, has been given to this fossil tree which seems midway between the Larches named above in the qualities of its wood.

The white form of *Wistaria multijuga* has been flowering profusely this year in Mr. Hunnewell's garden at Wellesley, Massachusetts, as well as in the Arnold Arboretum. It is a beautiful plant, perfectly hardy, and produces racemes of flowers varying from two feet to thirty inches in length. These appear after the flowers of the Chinese *Wistaria* have fallen and when the leaves are fully grown; they possess, moreover, a delicate fragrance hardly distinguishable from that of the flowers of the common Locust (*Robinia Pseudacacia*).

At the tenth annual convention of the American Seed Trade Association, held in Hartford last week, a communication was received from Mr. F. H. Mason, American Consul at Frankfort-on-the-Main, in which he stated that threatening letters from this country have been received by German seedsmen intended to prevent them from making an exhibit of their products at the World's Fair in Chicago. The association at once passed a resolution condemning all efforts of this sort and declaring that none of its members have ever participated in any such a movement. They expressed a hearty desire to have at Chicago the fullest representation of all the products in the world connected with their business.

The death is announced of Jacques Julien Margottin, a man known by name wherever Roses are cultivated, as his reputation as a rosarian, especially as a producer of new varieties, has extended throughout the world, and his nurseries at Bourg-la-Reine have long been famous for the collections of his favorite flower. In the long list of Roses which originated in his establishment the best known at the present time are Jules Margottin, Gloire de France, Triomphe de l'Exposition, Duke of Cambridge, Lord Palmerston, Madame Van Houtte, Belle de Bourg-la-Reine, Jean Goujon, Louis Margottin, Souvenir de Poiteau, Charles Turner, Triomphe de France, Gloire de Bourg-la-Reine and Henriette Pettit.

A bill authorizing the Governor of Massachusetts to appoint three persons to be known as the Metropolitan Park Commissioners has recently been enacted. It provides that these commissioners, who are to serve without compensation, shall consider the advisability of laying out ample open spaces for the use of the public in towns and cities in the vicinity of Boston, with authority to make maps and plans of such places, and collect all information necessary for acquiring, laying out and maintaining them. This is the bill which originated with the Trustees of Public Reservations, and its object is to provide some means by which the Middlesex Fells, the Blue Hills, and other tracts of wild unimproved land in eastern Massachusetts may be acquired for the benefit of the public.

The splendid Gladioli which now ornament all American gardens, from the finest to the humblest, when summer is at its height, are, as every one knows, natives of the Cape of Good Hope, greatly improved and infinitely diversified by cultivation. But perhaps it is not as generally known that the old-fashioned hardy species, bearing a few small rose-red or rarely white blossoms, which our grandmothers loved long before its showier cousins became the fashion, is of European origin, and is, indeed, a familiar field-flower throughout central and southern Europe. In those parts of southern France where the festival called the Fête Dieu is still publicly observed, its varieties are more generally employed than any other flowers to decorate the canopies borne in the processions and the little shelters where they halt.

"Nothing is more common," recently wrote Mr. Grant Allen, "than to see classical pictures of the Alma-Tadema school—not, of course, from the brush of the master himself, who is impeccable in such details, but fair works of decent imitators—in which Caia or Marcia leans gracefully in her white stole on one pensive elbow against a marble lintel, beside a courtyard decorated with a Pompeian basin, and overgrown with Prickly Pear or 'American Aloes.' I need hardly say that, as a matter of plain historical fact, neither Cactuses nor Agaves were known in Europe until long after Christopher Columbus had steered his wandering bark to the sandy shores of Cat's Island, in the Bahamas. But this is only one among the many pardonable little inaccuracies of painters, who thrust scarlet Geraniums from the Cape of Good Hope into the fingers of Aspasia, or supply King Solomon in all his glory with Japanese Lilies of the most recent introduction." It is well, of course, to have attention called to such anachronisms in art. But perhaps Mr. Allen will realize how difficult it is to be accurate in matters outside one's own special province when his notice is called to the amusing little architectural blunder he perpetrates in the paragraph we have quoted. It would be hard for either Caia or Marcia to lean, gracefully or ungracefully, against a marble lintel, since the dictionary defines lintel to mean "a horizontal piece of timber or stone over a door, window or other opening." What Mr. Allen meant to say was probably sill or jamb; and, doubtless, what the painter of King Solomon meant to paint was a Lily, not of Japan but of Palestine.

Restful Burial Grounds.

TWO articles published recently in these columns call attention to the charm of burial grounds where the attention is not distracted by decorations inappropriate to the scene, and the writer commends the Walnut Hills Cemetery, in Brookline, Massachusetts, and the Quaker burial grounds for their absence of showy adornment and monumental display.

We have already stated that it is the effort of superintendents and trustees of burial grounds to so dispose them that there may be a certain unity of design in their arrangement, and to make the parts subordinate to an agreeable whole; but there is a difficulty in reconciling the public to any interference with what seems an individual privilege, and it is hard to make people realize that what is of great significance to them may be a fatal blot in the whole picture as it presents itself to the general eye. But the education of taste goes on imperceptibly; given the canon, and in time it will commend itself to all; though the general instinct now is that every one has a right to express his sense of loss and his recognition of the value of the departed in such fashion as may seem to him appropriate. But, as in crowded grave-yards, the lack of beauty becomes more apparent as the work of the stone-cutter overpowers the work of nature, and this shows that somewhere a halt must be cried to personal fancy, and an endeavor made to introduce permanent beauty.

Those who remember the great cemeteries near our larger cities as they were fifty years ago, when their fine natural advantages of hill and dale, of wide outlook, or shadowy recess, were only here and there interrupted by grave-stones, and contrast them with their present aspect of closely crowded iron and marble, must regret that some controlling taste did not long ago intervene to preserve all that beauty by insisting upon monuments so small and unobtrusive that the trees and natural loveliness of glade

and elevation would still be the most apparent features of the spot rather than painful rows of glaring marble, often violent in design and imperfect in execution, or masses of flowers and colored leaves that are more curious than beautiful and appropriate. To this degree of taste people must be educated, and their expression of ornament controlled until they arrive themselves at the point where their own understanding commends a chaste and simple record of the departed in lieu of striking monument or elaborate inscription. What men like is a sure test of their æsthetic development and refinement, but even the artistic sense is the result of long and careful training and of constantly reiterated precept and of carefully studied example.

Since a cemetery must of necessity be conventional, as few monuments or grave-stones depart from some well-known and often repeated pattern, it seems right that such conventionality should be subordinate to a general plan which should combine all detail in one fair and noble conception of satisfying and restful beauty; so that a burial ground ought to be endeared to us, not only by the memory of those who sleep there, but by the grand groups of trees, the well-considered arrangements of shrubs and flowers appropriate to the scene, which would give to the whole ground a dignity and impressiveness forever to be associated in men's minds with those they have loved and lost. With the consciousness that years will increase and not detract from the beauty of the hallowed spot, affectionate thoughts can cluster around that serene resting-place, and draw us thither more and more willingly. For such a result canons of taste are imperatively necessary, and a few simple ones at least may be laid down for the guidance of those who earnestly desire to know what is truly befitting for so dear a spot.

In the first place it is admitted that no visible boundaries should be permitted between the lots, neither fences, nor hedges, nor copings of stone or marble, nor should the place where the dead lie be indicated by a mound.

A simple and artistic stone, ample enough for such inscription as is required, should be provided; but no tall conspicuous monument nor massive sarcophagus should be admitted, and it would be well if marble should be wholly excluded, as its keen whiteness is a constant shock to the eye, and always fails to blend harmoniously with surrounding verdure. Such shrubs and flowers as would be grouped here ought to be so disposed as to conduce to unity and breadth of effect. No individual desire to plant a rose-bush here, a willow there, should be permitted to interfere with a design which is not for the one but for the many, an effort to create one large and lovely dwelling for the dead, rather than a series of unlovely patches unrelated in design and ruinous to the general beauty of the scene by their lack of harmony with one another. It was this character of unobtrusiveness that inspired Gray's Elegy. The quiet graves where "the rude forefathers of the hamlet sleep" are destitute of stately monument. We can see the gray church with its clustering sunken stones about it today and realize the tranquil charm of that peaceful old churchyard, which needs no shining cenotaph nor glowing beds of flowers to make it live forever in our memory.

Restfulness and peace. What else do we need in our last home? Shall not the fresh flowers strewn by some loving hand upon our lowly couch be the best token we are unforgotten? Why, then, should our final sleeping-place be pranked out with marble and gaudy show of blossom? Rather let some quiet gray stone indicate our resting-place, and evergreen ivy drape it with its sombre leaflets, while over all may arch the boughs of ancient trees that shall bestrew it in spring with blossoms, and in autumn with the soft covering of its falling leaves. The reason for simplicity in burial places is obvious. It is not here that the memory of the wise and good is to be preserved. That lives in the minds of men. Here lies the common dust of which we all are made, and to which we are to return. Death, the great leveler, here makes an end of our pretences; before the Destroyer all are alike. Let,

then, the record be humble, since to this lot we come at last. All now are equals before the King, and efforts to maintain the distinction between lofty and lowly may well be dispensed with on our tombstones.

In a recent issue of this paper we spoke of the work of Messrs. Olmsted & Co. at the Columbian Fair, at Chicago, in connection with that of the architects to illustrate the true function of landscape-gardening or of landscape-architecture, as many members of that profession prefer to style it. We tried to show that very often the planting of trees, shrubs and flowers was a comparatively insignificant matter, a minor detail of a general design which is meant primarily to solve in a matter-of-fact way serious problems relating to comfort, health and convenience, problems of every-day practical and economical moment as well as questions of exterior appearance and adornment. Of course no one is competent to give advice on subjects of such vital importance to the owners of private grounds or to the people who make use of public grounds, without careful training. As we have pointed out, the profession deserves to rank with architecture among the arts of design, that it means something deeper than the making of pretty pictures on the grass, that the questions to answer are so weighty that no one has a right to assume the responsibility of facing them who has not added to an original aptitude and a correct natural taste the expert ability that comes from long and careful study. And yet there is danger that, as the value of counsel in this direction comes to be more generally recognized, there will be no lack of unskilled persons ready to call themselves landscape-gardeners, and to work untold harm upon confiding clients.

Not long ago a large sum of money was voted in one of our flourishing cities for establishing a park, and the regular administrative body who had the matter in charge promptly selected the foreman of a neighboring florist's establishment to make the design because he offered to do it cheaply. There was no question among these trustees as to his capability, because it was assumed that a man who knew all about the refinements of floriculture was master of the coarser work of "laying out grounds." A little reflection ought to have convinced these commissioners that a good design is always the cheapest; that even in this lower view of the matter the fee of a trained artist will always be saved many times over in the work of construction alone, while, after the plans have been carried out, the park will be constantly growing in beauty and usefulness as the years roll on. A plan which does not take advantage of all the possibilities of the situation and adapt them to the special needs of the city will be a disappointment at the outset. This means that the designer should be a man of wide intelligence and foresight as well as an artist in the highest sense of the term. An imperfect design will be a disappointment at the outset, and it will bring about an endless series of makeshift revisions and patchwork amendments, and, in a word, will be a costly failure. And yet there is no security now against the repetition of such mistakes.

In this profession, as in others, education must ultimately come through the improved taste of the people at large. Public works and private places will be at the mercy of journeymen until it is recognized that it is a fine art to design a park or to make the proper adjustment between a private dwelling and its surroundings so that the aspect and outlook of the house, its situation and its approaches and all its relations to the grounds shall be consistent, practical and in accord with the highest canons of taste. Even then there will be incompetent designers in this profession, just as there are architects who constantly sin against the very foundation principles on which true art rests. But the popular taste improves as good buildings are furnished for observation and comment; and popular taste in landscape-art will in time be educated, let

us hope, until there will be no place for quacks or pretenders in the profession.

Meantime it is the duty of every one who seeks professional advice in this direction to employ only those who have credentials which guarantee their competency.

A Corner in Pines.

THE planting of a bit of woodland teaches a great many virtues, but perhaps its most obvious lesson is that of patience, which it sometimes unexpectedly rewards just when one's expectations have been finally resigned as vain delusions. Such a reward and delight was ours in the result of a broadcast sowing of Pine-seeds in the autumn of 1888, so, for the comfort and cheer of those who may be downhearted about their own apparent failures, I wish to record the story of a final success.

When we started out to reclaim the worn-out old pasture on the hill at Overlea we set out a great many little evergreen trees of different sizes, a fair proportion of which survive in a vigorous condition, the smaller ones, planted when a foot high, being altogether the most satisfactory in percentage of survival. But Pines are queer; there is no denying that. Sometimes, when a tall weedy one was brought home, there were many jibes from the head of the family upon the folly of expecting such a specimen to stand the weather even for one season, while the merits of a stout, stocky, burly bush were highly extolled as a promising contrast. But now and then the burly bush succumbed, while the thin weedy tree pulled through, very much like some of those scrawny and tall New Englanders, who, though looking as if a high wind would blow them away, prove to possess a tough and staying quality which nothing in their looks presages.

Now, having had it affirmed as a fact that a hundred Pine-trees to the acre were enough if they all grew, nothing would really satisfy us but to put in a thousand to start with on about an acre and a quarter of stubborn soil. That is the true American spirit—a desire to overdo. Now, the master, having not much confidence in the methods of the mistress of this farm, concluded in true scientific spirit to begin at the beginning, and plant Pine-seed by the bushel, as the easiest and most thorough way of producing thousands of trees in a woodlot. It was in vain to quote to this opinionated person books on forestry, which stated that the results of sowing seed in the reforestation of France and Switzerland had proved less successful than planting of young trees; he was satisfied, like Sam Patch, that some things could be done as well as others, and that it was no reason at all that because seed was unsatisfactory in the effete countries of the Old World that it would not behave with perfect propriety in the more vigorous and self-respecting climate of Massachusetts, where all the hardy trees and virtues manage to get proper nourishment out of the most forbidding conditions. Therefore, furnishing himself with a barrel of Pine-cones, the doctor went ahead with his experiment.

It was quite a job to shell the seeds, but the factotum found time for this on rainy days in the late autumn, and when the light snow fell the sower went forth to sow, before the resin had time to harden in the seeds and interfere with their fructification. This part of the job accomplished, there was nothing to do but wait for Nature to do her part in furthering the experiment.

Spring came. Up popped little Oaks and Maples and Walnuts and Chestnuts that had been freely planted at the same time as the evergreens, but not a Pine condescended to appear. All through the summer belated nuts were putting in a tardy appearance, but still no Pines. Birds and field-mice were supposed to have devoured them, and we dismissed them from our minds.

A year elapsed. A few unhappy little Pines poked up their heads in sheltered holes, six or seven of them huddled together. We paid them frequent visits, encouraged them to live, piled sods about them to shade their poor little spines, but under an August sun in a very dry summer they withered away. By last year (1891) most of them had disappeared, and there was some scoffing on my part and quotation of authorities to emphasize the fact that Pine-sowing was no good, which the experimenter bore with becoming meekness, while counseling me to wait. But this I concluded was only by way of argument, and because no man likes to admit that he can be beaten by the forces of nature—namely, birds and field-mice.

But in this year of grace, 1892, lo! a miracle took place! When the March winds had ceased to blow and the snow had melted, so that we could walk abroad over the uncut brown grass upon the hill, what should we spy peering up beside the

withered Golden-rod stalks and the ghost of last year's Daisies but thousands of six-inch Pines, rearing their gallant little heads, undaunted by the weather, and evidently come to stay. We hailed them with shouts of delight—here a clump, there a single one, crowding closely in the mossy springy places, more scattered where the soil was thin; but unmistakably there, after all these years of waiting, evidently quite at home, having hidden themselves in the long grass of the preceding summer, while they had been sending down roots so far that when we try to separate some of the denser groups it is really hard to dig them up with a trowel without injuring their fibres.

My scientific companion magnanimously forbore to triumph; indeed, the proud result was as unexpected to him as to me, and was so gratifying that he could afford to accept it with quiet satisfaction.

Some of these little trees, in a spot sheltered from the north-east wind by a clump of tall Birches, have attained respectable proportions, so that we ventured to move them into separate holes. Though taken up on a cool evening with a ball of earth, and apparently no disturbance of their roots, the perverse things wilt and hang down their heads as if they were ready to misbehave, which they have no excuse for doing. On one evening we moved twenty-five very little ones, which all grew in one hole, and most of them bore it very amiably, though some of them perished. As these would have died any way, if left alone in the struggle for the survival of the fittest in that little space, we bore their loss as well as we could, though I must admit that your true planter cannot see the death of one seedling with indifference, which gives a new meaning to the text that "not a sparrow falleth to the ground without His knowledge." If he who plants mourns the failure of one tiny seed, it helps to the understanding of the Creator's interest in all the creatures into which He has breathed the breath of life, for, after all, those of us who struggle to bring to birth or to keep in existence some germ of vegetation approach the great mysteries of being, and feel that we have a hand in it.

Our corner in Pines teaches us a brave lesson. Our joy in our little wood-lot, with its fairy trees, is the greater for being long delayed. What comes easily never has the zest of the pleasure that is waited for. We value a result by the difficulties of its achievement, the triumph of its success. An acre of unsown Daisies is a trial, while a square foot of planted Pines is a satisfaction, showing that a longed-for and slowly reached result is in itself a reward. Our Pines represent the achievement of birth after long and almost hopeless waiting. It is not so much the thought of the majestic forest that consoles as the assured fact that the unstayable seed has started and that it has a future before it. Under the old tree we sit and look back; it represents shelter and repose and peaceful satisfaction. Beside the seedling in its various stages we stand and watch; in it is hope, a future, a long look forward. Age and youth; in each an interest and a joy. In one the delight of fruition, in the other the splendid promise of birth and growth. In the establishment of a tree for coming generations there is an unselfish delight. It is not our own reward we seek, but we lend ourselves to the great forward movement of life, and in that creative instinct feel ourselves elevated and enlarged, at one with mighty forces which we cannot understand, but of which we can avail ourselves by directing their vivifying course.

It is this linking of the humblest with the greatest that lifts existence above the commonplace; that gives to the philosopher, the poet and the artist an ever new meaning and joy in the common things of the earth, which, to him who reads aright, are fraught with significance. To the thinker, as to the poet, the simplest things serve as types which represent the infinite; to them the humble is the high, the microscope as inspiring as the telescope, since each reveals new worlds to the imagination. The seed contains the germ of the tree. One Pine-cone in time will produce a forest, for the progression is geometrical. One acre of ground faithfully studied gives one the key to the problem of the universe; helps to a recognition of the miracle of creation, and, rightly valued, affords perpetual food for the intelligence, while supplying the body with lively exercise.

From our corner in Pines we win hope, amusement and patience. It opens for us a window into the future and an outlook into the immensities; it links us with a hereafter we shall not live to see; with a generation by whom our names shall be forgotten, and proves to us the truth of that vision of the poet, in which he sees that

The whole round earth is every way
Bound by gold chains about the feet of God.

Hingham, Mass.

M. C. Robbins.

The Great Elm at Derby Line.

THE Elm figured on page 307 is doubtless the largest tree in Orleans County, Vermont, if not in all the north-eastern part of the state. It is, unquestionably, a tree of the original forest; and it was, to the eye, nearly as large in all its dimensions when the region was first settled, in the early part of the present century, as now. Its height, by careful measurement, is 102 feet. Three feet from the ground its circumference is exactly twenty feet, while at five feet it is eighteen feet and two inches. Its comparatively small head is probably due to the fact that it grew in a close forest and had no opportunity to spread.

It stands close to the highway, which is also the main street of the village of Derby Line—so named because this street extends to the international boundary line between the United States and Canada, and is continuous with the main streets of Rock Island and Stanstead, Canada. Rock Island is situated upon an island in the Tomefobi River, which is almost exactly on the line at this point, and Stanstead Plain is a village closely adjacent on the north bank. The whole territory for fifty miles around consists of the finest agricultural land. On the Canadian side it is known as the Eastern Townships, in large part settled by New Englanders, who, before the line was strictly defined, "made their pitches" without much regard to where their citizenship and allegiance might fall. In addition to this Yankee element there was a large introduction of English immigrants, mostly soldiers from the disbanded armies of Great Britain after the final overthrow of Napoleon I. There is only a moderate intermixture of the French Canadian element in this part of Canada, and its principal town, Sherbrooke, now a city of some 12,000 people, is substantially of British antecedents and environment.

All this region (as also the valley of the great St. John River, in northern Maine and New Brunswick) consists of what is known as "hard-wood land," although, of course, with much mixture of Pine, Spruce, Fir, Hemlock and White Cedar (*Arbor-vitæ*). It is a rolling, well-watered section, the chief rivers on the Canadian side—the St. Francis and Chaudière, with their tributaries—and many lakes, large and small, leaving the traveler through it not often out of the sight of water. Altogether it is a pleasant land, peopled by an excellent class of farmers, with a considerable manufacturing element on both sides of the line. The vigorous growth and great size of the trees testify to the fertility of the soil, and for general farming, it and its continuation eastward constitute decidedly the best portions of the great peninsula lying east of the Hudson River and Lake Champlain.

Plant Notes.

Some Recent Portraits.

IN the June issue of *The Botanical Magazine* are portraits of *Althæa ficifolia* (t. 7237), a native of south-eastern Europe and the Levant, a handsome Hollyhock, long known in cultivation, differing principally from the well-known *Althæa rosea* in the narrow lobing of the leaves, an uncertain character hardly to be depended on to distinguish the species. As a weed of cultivation this plant extends from Persia to Siberia, southern Russia, Servia, and Egypt, and is believed to have originated in north-western Persia. It varies from a few inches to five feet in height, while the flowers vary in color from pale yellow to purple. *Eria marginata* (t. 7238), a little-known Orchid originally described from a solitary specimen believed to have been introduced from Burmah. It belongs to the small section *Hymenolæna*, with cylindric or clavate stems, a few sub-terminal leaves, short peduncles, and large colored bracts. Sir Joseph Hooker points out its relationship to the Khasian *Eria clavicaulis*, which has a small rounded mid-lobe of the lip margined with purple, and to the Ceylon *Eria Lindleyi*, of which the lateral lobes of the lip reach almost the same length as the terminal. It is a small-flowered plant of no great beauty, with white sepals and petals and a lip bordered with red, the middle lobe being light orange color. *Senecio Galpini* (t. 7239), a native of the Transvaal Republic and a rather showy succulent plant with pale leaves and dark orange flowers in dense heads. *Porana paniculata* (t. 7240), a member of the *Convolvulus* family and a native of the East Indies, with small light yellow

flowers in dense compound cymes, in the hot Himalayan valleys climbing over trees to a height of upward of forty feet, and sending down showers of pendulous flowering branches from above; it is described as one of the smallest flowering species of the genus, differing from its congeners in the short style and solid stigma. Eight species of *Porana* are known in India and are spoken of as the most beautiful hedge-plants of that country; two of them are particularly abundant—the species here figured, which abounds from the base of the Himalaya throughout its length to Ceylon and Burmah, reappearing in Java, and *Porana racemosa*, the “Snow Creeper” of Anglo-Indians, a plant confined to the Himalaya slopes, where its masses of dazzling white flowers recall patches of snow. *Porana grandiflora* ascends to eight thousand feet in the Sikkim Himalaya and produces mauve flowers an inch in length. *Rosa pomifera* (t. 7241), a handsome species distinguished by its large succulent fruit from which it has been cultivated from time immemorial.

Begonia Haageana is handsomely figured in *The Garden* of June 4th. This is a beautiful perennial, perpetual-flowering *Begonia* introduced a few years ago from Brazil by the nurseryman of Erfurt in Germany, whose name it bears. It is described as one of the most magnificent of the many *Begonias* known and to be as easily cultivated as a *Coleus*. At Kew there are specimens four feet high and nearly three feet through, clothed with leaves from top to bottom, and covered with flowers, although the largest heads of bloom are produced in autumn, when they sometimes measure a foot in diameter. The male and female flowers are usually borne on separate cymes and are remarkable from the fact that the females do not fall off but remain on the plant until they become green even although not fertilized. This will probably be found one of the most useful of all the winter-flowering *Begonias*, and its early introduction into the gardens of the United States is certainly desirable.

In the sixteenth number of the American edition of *Lindenia*, Monsieur Linden's magnificent Iconography of Orchids, are figures of *Eulophiella Elisabethæ*, an interesting plant with the general habit of a *Catasetum* or of a *Eulophia*, but which, from the peculiar structure of the flower, is considered the type of a new genus. The stout pseudo-bulbs produce four lanceolate leaves attenuated below into slender petioles and nearly two feet in length with prominent veins. From the base of the pseudo-bulb the scape rises to the height of nearly a foot, and like the fleshy concave bracts and pedicels is a deep vinous purple, making a handsome contrast with the white flowers with broad spreading segments, which form a nearly complete circle. The generic name of this interesting plant serves to indicate the resemblance to *Eulophia* and also the presence of the peculiar conspicuous crest. The species is dedicated to Queen Elizabeth of Roumania, and was introduced by the Horticulture Internationale of Brussels, where it has recently flowered. The native country is not divulged, although we are told it should be grown in a warm house and that it will succeed under the treatment needed for *Phajus*, *Eulophia* and *Cyrtopodium*.

There are also figured in this issue *Phajus tuberosus*, a beautiful Madagascar species, which in recent years has excited the admiration of Orchid-growers; *Cypripedium exul*, var. *Ilshootianum*, a plant at first supposed to be a variety of *Cypripedium insigne*, to which it bears, in the general form and color of the flowers, a remarkable resemblance, although it differs from that species in its erect, not spreading, leaves; and *Peristeria Lindeni*, a remarkable and striking species with short racemes of almost globular flowers with light green sepals and petals suffused with dull purple, and covered throughout with deep dark purple spots, the lip being margined and striated underneath with the same color on a pale ground. This very striking and interesting plant is a native of tropical America, whence it was introduced by the Messrs. Linden.

New or Little-known Plants.

Hypericum opacum.

AMONG the American *Hypericums* are several species which commend themselves to the attention of gardeners. The species are all dwarf shrubs with deciduous leaves, and produce an abundance of showy yellow flowers from midsummer to early autumn—that is: at a time of the year when few shrubs are in flower.

We have, from time to time, published portraits of several species, which, curiously enough, are little known except to professional botanists, and in the present issue another species is figured (page 305). It is the *Hypericum opacum* of Gray, a southern plant, with a range from South Carolina to Tennessee and to Florida and Mississippi, and produces erect slender stems one to four feet high, covered with light red exfoliating bark and corymbosely branched toward the summit. The leaves are closely sessile, linear-oblong, obtuse, pellucid punctate with crowded dots; an inch or an inch and a half long and a quarter of an inch broad. The flowers, which appear in nearly naked divaricate cymes, are rather less than half an inch in diameter. The seed-pod is ovate and a quarter of an inch long, and the seeds are oblong and minutely pitted.

Hypericum opacum is less hardy at the north than many of the other species; it will, of course, flourish in the gardens of the southern states, and may be expected to thrive as far north as the neighborhood of this city. C. S. S.

Foreign Correspondence.

Knap Hill Nursery.

THIS nursery is famous the world over for its Rhododendrons and hardy Azaleas, and Mr. Anthony Waterer, its venerable proprietor, is one of England's most noted gardeners. To see the Rhododendrons and allied plants in the Knap Hill nursery in June, with Mr. Waterer for a guide, is to enjoy one of the most magnificent floral displays it is possible to conceive, and to hear a great deal of exceptionally interesting information about them. “The Knap Hill nursery is the most extensive, as it is the oldest, establishment in England in which the cultivation of American plants has been made a specialty. Its extent exceeds 200 acres, of which more than 60 acres are allotted to the cultivation of American plants. The beds and borders devoted to this class of plant extend over miles in length and contain the largest quantity of the finest plants to be met with in this country or in Europe.” This is word for word what Mr. Waterer says in his plant catalogue, and it is a modest enough description to any one who has seen Knap Hill. The nursery is well situated in regard to soil and water, and the position, though bleak, is fortunate in the surrounding scenery, which is of the delightful Surrey hills and dales. Running straight through the nursery there is a very long carriage-drive connecting two public roads, and this drive Mr. Waterer generously permits the public to use, with certain reservations as to dogs, etc. Thousands of people go every year to Knap Hill to see the wonderful display made by the Rhododendrons and Azaleas. Whit-Monday is quite a gala day, the crowd being so great that the workmen of the nursery have to act as patrols to keep the visitors in order. To understand all this one must see the plants for himself. I had no idea that the display was so magnificent, and I do not expect to succeed in conveying to others anything like a fair idea of this wonderful collection of outdoor plants. There are masses of Rhododendrons, Azaleas and other similar plants in other nurseries, in public gardens and parks, and in private establishments, but they are insignificant when compared with the Knap Hill collection. Of course, when it is remembered that these plants have been a specialty in this nursery for more than a century, that the best varieties have nearly all been raised there, and that the Waterers have always been

what is called *Rhododendron mad*, the extent and interest of the collection are to some degree accounted for. Mr. Waterer is a conscientious breeder; he will have nothing to do with plants of inferior quality. "I like a *Rhododendron* or *Azalea* flower to look me in the face, to spread out its petals, and to pack in the truss so that it never flops about in rain or wind. It must have good leaves too, be fit to look at when out of flower, and be absolutely hardy. We

Mr. Waterer has annually large exhibitions of *Rhododendrons* in the gardens of the Royal Botanical Society at Regent's Park, and in Hyde Park near Rotten Row. These latter I saw a few days ago, and exceedingly attractive they were. Some of the specimens were enormous, one of the rich blood-red flowered *Michael Waterer* being a truly wonderful picture. It was nine feet by nine feet, and literally crowded from top to bottom with huge trusses of flowers which almost dazzled the eye. But there are better things than this even to be described in the nursery.

The *Azaleas* are grown in hundreds of thousands, from young plants flowering for the first time to huge specimens almost as large as a haystack. Colors of every shade, from white to orange and crimson, some variegated, some self-colored, some of dazzling brilliancy, others delicate, but all lovely. Flowers as large as those of *Azalea Indica* were plentiful among the more recent seedlings. Later-flowering varieties than the old *Calendulacea* family have been raised chiefly from *A. occidentalis*, and are being rapidly propagated by Mr. Waterer. They flower fully three weeks later than the older kinds. The parent of all Mr. Waterer's red-flowered seedlings is what he calls *A. coccinea*; really, I suppose, a form of *A. calendulacea* with deep red flowers. There are several magnificent bushes, the originals of this variety, at Knap Hill. None of these *Azaleas* are grafted; they are mostly raised from layers or seeds. Many of the colors appear to come fairly true from seeds. In England, at any rate, we do not use these grand *Azaleas* nearly as extensively in gardens as they should be used. If Mr. Waterer had done nothing else, his work in improving and diversifying the American *Azaleas* would certainly prove a lasting monument to him.

A. Sinensis (mollis) is also receiving special attention at Knap Hill. As a flowering plant it is as fine as the very best of the American kinds, and in England, at any rate, it is perfectly hardy. Already Mr. Waterer has obtained varieties with blood-red flowers. I consider this *Azalea* one of the very best garden-plants in the genus. Very queer, yet promising, crosses have been made at Knap Hill, of which, however, I may not say more than that they are likely to add to the fame of the Knap Hill establishment.

The *Rhododendrons* take one's breath away. Is there any genus in the whole vegetable kingdom to which gardens are so much indebted as to *Rhododendrons*? Outside, in the greenhouse, the intermediate house, and even in the stove, we have them, and they are almost every one beautiful. But if this is true with regard to species, what might one say of the hundreds of splendid crosses which we now possess? I was ignorant of the endless variety of color, beauty of form

and grand character generally of the hardy *Rhododendrons* until I saw them the other day at Knap Hill. Almost every color, even to blue and almost to black, is represented. But to see what these plants are capable of, one must behold them when grown into huge bushes and covered with trusses of flowers. Of course, the soil at Knap Hill exactly suits *Rhododendrons*; the plants there attain a perfection which it is hopeless to expect in less

Fig. 54.—*Hypericum opacum*.—See page 304.

send no plants out of this nursery that do not fulfill these requirements." When asked what kinds did best in colder regions, for instance, in the northern states of America, Mr. Waterer replied that he bred only from *R. Catawbiense* for America, and that he would never recommend the tenderer sorts for that country. But, he exclaimed, "they know all about my *Rhododendrons* and *Azaleas* too, for we send thousands to the Americans every year."

suitable soils or within range of the smoke of large towns. But these plants are not dear, even if one has to renew them every few years. We do not hesitate to spend fifty pounds in the purchase of Tulips and Hyacinths for a week or two's display in spring, and this sum laid out in Rhododendrons would produce something at least equally as attractive and lasting. But, as Mr. Waterer says, Rhododendrons and Azaleas will succeed in almost any soil that does not contain lime or chalk, and in many sandy loams they grow with as much vigor and luxuriance as they do in peat.

I set down the names of the Rhododendrons which I saw and thought excellent. They were as follows: White, Rosalie Seidel, Sappho, Mrs. S. Simpson, Mrs. J. Clutton, The Queen; rose or lilac, Everestiana, Marchioness of Lansdowne, Lady C. Mitford, Alexander Dancer, Lady Grey Egerton, Stella; scarlet, J. Mackintosh, Mrs. Shuttleworth, E. S. Rand, M. H. Sutton, Doncaster, J. M. Brooks; crimson or purple, Cetewayo, Melton, G. Paul, John Walter, Sigismund Rucker, Michael Waterer, *Purpureum grandiflorum*, King of the Purples, C. S. Sargent, Sir Hugo. These are all sterling sorts, such as I would like to plant in quantity in a garden for myself. In a nursery where bad or inferior varieties are not cultivated it is almost superfluous to make selections. To stand on an elevation at one end of the nursery and look over the whole extent of Rhododendrons is to see the full splendor of these plants, a splendor which, in my opinion, is unequaled even by the Rose.

The propagation of Rhododendrons is partly from layers and partly by grafting, the former, although slower, being preferred by Mr. Waterer on account of the suckers which grafted plants are almost certain to develop to the injury and even destruction of the cion. The renovation of sickly or worn-out specimens by cutting them in hard, and sometime by grafting better sorts upon them, was described and shown to us by the young Mr. Anthony Waterer, who is as keen a grower and admirer of American plants as his father.

In June everything at Knap Hill is eclipsed by the Rhododendrons and Azaleas, but if one can afford the time an inspection of the other plants in the nursery is of more than ordinary interest. Nothing but what is good, and almost everything in fine health and form among Coniferæ, forest-trees, ornamental trees and shrubs, and even herbaceous plants may be seen here as one rarely sees them. I noted variegated Turkey Oak, Double White Thorn, Weeping Thorn, *Adrus atlantica glauca*, a beautiful *Laburnum* called Waterer's, remarkable for length of raceme and color; a huge tree of the Golden-yellow Chestnut; another of the Crested Beech, and one of the evergreen *F. antarctica*; a Weeping Beech, thirty feet by sixty feet, which is said to be only about sixty years old, and is one of the most wonderful trees in the nursery. Thousands of the Blue Spruce (*Picea pungens glauca*), of Golden Yews, Cypresses, and many other conifers; *Acer Worleyi*, with rich bronzy leaves; *Alnus Van Houttei*, yellow; a fine deep-colored red Horse-chestnut, called *Æsculus rubicunda rosea Brioti*; the silvery *Pyrus sorbus*, var. *lutescens*; grand forms of *Cydonia Japonica*; Weeping Purple Beeches, and very fine Hollies. I might run through almost the whole of the numerous plants enumerated in Mr. Waterer's catalogue, and state that all were first-rate. A form of *Spiræa Bumalda*, called the Knap Hill Scarlet, is one of Mr. Waterer's new plants with a promising future. It has scarlet flowers in large compact heads, and blooms from July until destroyed by frost. Old, and in some cases unique, specimens of many trees are scattered about over the nursery, and impart to the place an appearance unusual in trade establishments. The preparation of the plants for removal is done systematically and thoroughly, so that large specimens can be transferred to other gardens without much danger of failure. Some of the best of our newer gardens have been planted with material supplied from Knap Hill. The garden at Waddesdon Manor, the residence of Baron

F. de Rothschild, considered by competent judges one of the best gardens in England, was stocked principally by Mr. Waterer.

Iron-clad Stocks—The Graft-box Fungus.

I AM much pleased to find that my proposal to employ iron-clad seedlings as stocks for budding or grafting tree-fruits for the cold north meets with the endorsement of Professor Budd, of the Iowa Agricultural College, who has made a special study of the best methods of propagating fruit-trees in the north-west, and who is a well-known experimenter with the so-called Russian varieties of fruit-trees. Referring to my remarks on this topic in a recent issue of GARDEN AND FOREST, Professor Budd says in *Rural Life*: "Beyond all doubt budded Apple-trees on hardy roots would prove more valuable than our ordinary piece-root grafts. In practice it would also be a source of gain to the nurseryman. Budded trees, when two years old, are larger and smoother than root-grafts three years old, and the number of culls among budded trees would be small—not one-tenth the number found among piece-root grafts where third cuts are used."

While defending piece-root grafting from what seemed to me unreasonable criticism, I have always opposed the use of third cuts, or even second cuts from small roots. But I shall hail with joy the laying away of this controversy by the adoption of a class of stocks which will allow of budding the iron-clads in place of grafting them. Heretofore this has been impracticable, because it brings the stock above ground, and unless the iron-clads budded on common stocks are planted out in the orchard so deeply as to well cover the point of union, the young trees are no hardier than their stocks.

In order, however, to obtain iron-clad seedlings fit for budding valuable market fruit must be used at a loss unless it is evaporated and the seed saved from the cores; and even this makes much more work in extracting the seed from the cores, compared with ordinary cider-mill seed. But at a dollar or two per pound such seed will be cheap for all nurserymen who are growing budded stock for planting where the thermometer goes down into the minus thirties and lower nearly every winter.

On the subject of the "graft-box fungus" Professor Budd advises keeping the grafts in a low temperature, even considerably below freezing; and a long experience has taught me that grafts so kept winter in fine condition, and grow strongly when planted out. So particular have I been about this matter that when I have had root-grafting done by others I have insisted that the grafts be made early in the winter, and sent to me as soon as made. A single neglect of this rule cost me the loss of a considerable lot of grafts of one of the new Russian Pears. When received from the grafter, early in April, they were nearly all started. Though very carefully put out, only a few grew, and of these none made a satisfactory growth or became merchantable.

The chief difficulty in wintering root-grafts, aside from temperature, arises from variations in the moisture of the packing. When fine sawdust direct from the green log is used, carefully packing it about and between the bundles of grafts, containing not more than one hundred each, the boxes closely covered and kept in a freezing temperature, the grafts will afterward be found in perfect order, and no sign of the fungus makes its appearance. This statement is based on an experience of more than twenty-five years. On the other hand, if the grafting is carelessly done, with unnecessary exposure of stock and cion to heating and drying influences, and then the completed grafts, in large open bundles, are packed loosely in a mixture of chopped straw and wet sawdust, and kept in an even moderately warm cellar, either the grafts will be attacked by the fungus, or they will become too dry, or their buds will swell and grow—any one of which occurrences is fatal to that vitality upon which, with careful planting, we must depend for a stand of marketable young nursery trees. On light soils particularly, but also on any soil suitable to the purpose, a vigorous growth of the grafts depends largely upon deep, careful and firm planting. One good bud above the surface is better than more. The soil should have been several years in tillage, deeply plowed, and abundantly and evenly enriched from the surface downward. In this way we get very fine trees from carefully made, kept, and planted root-grafts. But with good iron-clad stocks, still better results may be attained by budding.

Newport, Vt.

T. H. Hoskins.

Choice Herbaceous Plants.

ST. BRUNO'S LILY, *Anthericum liliastrum*, is not only perfectly hardy in this locality, but it grows freely and produces an abundance of snowy white lily-like flowers. It is a first-class ornamental and useful plant, and deserves to be more generally grown. Perhaps one reason why it is not seen oftener is that those who grow it usually have but one specimen, and in this way it is never so effective as when grown in

masses. This *Anthericum* is a native of the Alpine meadows of the south of Europe, and has been in cultivation since 1629. It grows about twenty inches high, and its leaves are about twelve inches long. The white flowers are fragrant, two inches long and about one and a half across, and on the point of each of the petals there is a small green spot. The flowers are produced in loose spikes, each spike bearing from six to twelve flowers. The variety of this plant called Major very closely resembles the type, but it is a stronger grower and has

Fig. 55.—The Great Elm at Derby Line, Vermont.—See page 303.

masses. To insure a good effect requires a clump at least two or three feet in diameter. A few days ago I saw such a group at a nursery near here, and the flowers showed to great advantage above the abundant foliage. The plants thrive best in a deep rich soil, and they are not particular whether they are placed in a partially shaded position or in full sun. I find that the plants somewhat shaded come into flower a little later than those which receive the full benefit of the sun. If we have plants both in sun and in shade a longer season is in-

larger flowers, which are produced in profusion, and are very useful for cutting purposes. Both type and variety are propagated by division of the roots in the fall, or by seeds, which should be sown soon after they are collected. This plant is also known under the name *Paradasia Liliastrum*.

The genus *Heuchera* is a small one, consisting of about twenty species of hardy perennials, and belongs to the Saxifraga family. They are all natives of temperate North America. The flowers of most of the species are neither showy nor orna-

mental, but they form compact tufts of foliage, which are rather pretty, and can be used to advantage under taller-growing subjects. *Heuchera sanguinea* is the best plant of the genus, and it has come to be ranked as one of our best perennials. It is a robust grower, perfectly hardy, and does not require any special treatment, growing freely either in the herbaceous border or in the rock-garden. When it is planted in a mass it gives a splendid effect. It is comparatively new, having been introduced into gardens from Mexico in 1882. It has a neat bushy habit, forming compact tufts of leaves close to the ground. The graceful flower-stems are produced abundantly, and are covered with deep red tubular flowers, which last for several weeks. The leaves are light green, slightly hairy, cordate, five to seven lobed, and these are again sharply crenated. It is easily increased from seed or by division of the crowns in spring.

The Alpine Aster (*Aster Alpinus*) has large bright purple flowers which are much admired. It is a neat and beautiful plant, growing from nine to twelve inches high. The flowers are produced singly on the stem and are about two inches across. This Aster is a very old inhabitant of gardens, having been in cultivation for over two centuries; and yet in some of our best collections of hardy plants it is not seen. It is not hard to grow if placed in good garden-soil where it can have plenty of light. It is an excellent plant for the rock-garden or the front row of the herbaceous border. After the flowering season it may be increased by division of the strong roots or by seed.

Several of the species of *Campanula* are just now conspicuous in the borders. *Campanula persicifolia*, with its large blue flowers, is very showy and making quite a feature where there are large masses planted. There are several varieties of this plant, such as *Alba*, *Maxima* and the double white, and all of them are good garden-plants. *Campanula glomerata* *Daurica* is a good plant, flowering annually with great profusion, and demanding little care or attention. It was brought from Siberia in 1825, and was thought then to be a new species, but was afterward reduced to the rank of a variety. It grows from fifteen to eighteen inches high and has large deep purple flowers, produced in dense heads. All these species and varieties are easily cultivated; they do well in a good, rich, open soil, and are increased by division of the plants either in the fall or spring.

Centranthus ruber is an old favorite and is covered just now with its red flowers. It belongs to the Valerian family and is sometimes called the Red Valerian. It is a native of the south of Europe and is naturalized in Great Britain. The plant attains a height of two feet here and is a little shrubby at the base of the stem. The individual flowers are very small, but they are produced in dense cymes forming a handsome corymbose panicle, and are very useful when cut, as they last for several days. There is a white variety of this plant which is quite pretty but does not come into flower as early as the species. This plant will grow in any sort of soil, but to get the largest and brightest flowers it needs a little manure. It is most readily propagated in the fall by division of the roots, great care being taken to preserve the long fleshy roots and to break or bruise them as little as possible.

The perennial *Spiræas* are just now among the best ornaments of the herbaceous border. *Spiræa Aruncus* is one of the tallest and most showy, growing to a height of four feet. Its habit and foliage are good, and its small white flowers are borne very freely on long spikes, forming a terminal panicle. It does well in the border or wild garden associated with the more vigorous perennials; but it requires to be planted in deep moist loam. It is a native plant, but is also found in Europe and Asia.

S. astilboides is another handsome perennial which is rather like *S. Aruncus*, but is much more dwarf and graceful. It grows about two feet high and its stems are furnished with triternate leaves and terminated by spicate panicles of white flowers. As a border or rock-garden plant it is unrivaled among the dwarf *Spiræas*. It is also very useful for forcing in spring, making a good pot-plant, growing freely and flowering profusely. It is a comparatively new plant and was brought from Japan a few years ago. The Dropwort or *Spiræa filipendula* is a European species and received its common name on account of its small tuberous roots hanging like drops by slender threads. There is a double form of this plant which is more common in gardens than the species. The flower-stems are about two feet long and all in loose panicles; the flowers are white and are very useful for cutting. The foliage is very pretty and fern-like; it is mostly radical on the lower part of the stems. It is a good border-plant. It is very pretty in our rock-garden, where it is planted in a high and open po-

sition, so that its large panicles of double white flowers show to great advantage. All the herbaceous *Spiræas* are easily multiplied by division of the plants.

Cambridge, Mass.

Robert Cameron.

Fern Notes.

COMPARATIVELY few noteworthy Ferns have been introduced during the past year or two, and most of these are in the line of variations of well-known types. Some, however, prove to be decided improvements, and as such are worthy of more extended cultivation; among these is still another form of the old Ribbon Fern (*Pteris serrulata*), known as *P. serrulata cristata densa*, an unfortunately long title for so pretty a Fern. This variety is in the style of *P. serrulata Dixonii*, but is more compact and profusely crested, the fronds being gracefully arched and of light green color. It will no doubt prove a useful plant for small ferneries, and as the various forms of this species are among the easiest to propagate, a stock may readily be secured.

Pteris Cretica Mayii is not new, though it is not very common; it presents some of the well-known characteristics of the type in its hardy nature and tough foliage. It also is compact in growth, the fronds being short and the pinnæ more or less forked and crested, their color being dark green, with a slight variegation of lighter color down the centre of each division. *Pteris Cretica nobilis*, also a good form, does not produce as many spores as do some other varieties of this class, and has, therefore, not as yet become so popular a plant as was anticipated, though unquestionably a very serviceable variety.

Some of the newer forms of *P. tremula* become very attractive plants when carefully grown, and either for conservatory decoration or for exhibition purposes have much value. *P. tremula Smithii* is one of the best, and the fronds are finely divided and much crested on the tips of all the segments. This variety is, I think, more graceful in habit than *P. tremula grandiceps*, an earlier crested form of this species, already described in GARDEN AND FOREST.

The *Adiantums* also continue to produce cristate forms, among those of recent introduction being one of *A. assimile*, the fronds of which are tipped somewhat like those of *A. cuneatum grandiceps*, and, like that variety, have an effect both curious and graceful. This form of *A. assimile* will probably make a useful basket Fern, the type being specially adapted to that method of cultivation.

Pteris Victoriae is certainly one of the prettiest Ferns of recent introduction. The variegation of its slender fronds is clear and distinct in its markings, while the habit of the plant is neat and graceful. The growth of this species is moderate, and it is well suited for small collections. It enjoys more heat than many other members of the genus, doing well in a temperature of sixty to sixty-five degrees. This is the Fern discovered by Mr. Forstermann in a warm locality in the South Pacific islands during one of his Orchid-collecting tours.

Gleichenia dicarpa longipinnata is one of the most beautiful Ferns, and deserves a place wherever the proper facilities for the growth of these plants exist. It is not new, but as the *Gleichenias* are usually propagated by division of the rhizomes, their multiplication is naturally slow, and special forms continue somewhat rare. This variety has very long fronds and small pinnæ, and makes a most attractive specimen, but, like nearly all its fellows, *G. dicarpa longipinnata* thrives best in a moderately cool house.

G. rupestris glaucescens is another useful form, and, like *G. dicarpa longipinnata*, is of scandent growth, but has much coarser fronds of light green color, and is quite glaucous beneath. It bears some resemblance to *G. Speluncæ*, but is not so strong a grower, and will flourish with more heat. *G. dicarpa* frequently bears spores, from which I have sometimes succeeded in raising seedlings, but I have never seen spores on *G. Speluncæ*.

W. H. Taplin.

Narcissus poeticus.

THE Rev. G. H. Engleheart, in writing to the *Gardeners' Magazine* of *Narcissus poeticus*, which brings the Daffodil season to a close, calls attention to the great length of that season. The little Hoop-petticoat *Narcissus* will flower in England under glass in February, and such precocious kinds as the Golden Spur and Tenby, under the shelter of a south wall, will begin to bloom in the middle of March, while June will find the last of the Daffodils, the Double Poeticus, in bloom. The Pheasant's-eye Daffodil,

or Poet's Narcissus, is cultivated in England by the million in the open ground, especially the early-flowering form, *Ornatus*, but, well known as it is, it has been strangely neglected by hybridizers. It has been crossed with the Trumpet Daffodils, and the result is apparent in the numberless short-crowned flowers of the *Incomparabilis* section, but there has been little attempt to enhance the best features of the Poet's Narcissus, as has been done with the Trumpet Daffodils, by intercrossing and selecting seedlings. Just as that splendid plant, the Emperor, is probably only an improved form of the old Narcissus *Rugilobus*, or *R. lorifolius*, so a more robust and floriferous race of Poet's Narcissus with red eyes might be secured, and, indeed, has been secured by Mr. Engleheart. He has also obtained flowers with the shapeliness and precocity of the *Ornatus* varieties, but much increased in size, besides crosses between *Ornatus* and the late *Recurvus*, which unite in the same flower the brilliant whiteness and solidity of the latter with the flatly expanded form of the former. But there is abundant room for other workers, and this field is more promising than any other in Narcissus culture, because every seedling of *N. poeticus* has a vigor, a constitution, if it has no other good quality. Of the cultivation of the Pheasant's-eye Daffodils, Mr. Engleheart says:

In the cultivation of the Pheasant's-eye there are three points which should be kept in mind. First, its great inherent vigor enables the plant to thrive in a much richer soil than is wholesome for most other Daffodils. Broadly speaking, no amount of manure will injure either blossom or bulb. To those who have the common variety, *Recurvus*, or late single Pheasant's-eye, in their gardens, but grown as it usually is—namely, left alone for years in a half-starved condition in a mixed border—I recommend planting a batch of bulbs in a slip of deeply-dug and heavily manured kitchen-garden ground, and lifting and replanting annually in similar quarters. The change of the flower in dimensions and substance will astonish them; indeed, it becomes a different thing altogether. The second point is that all the Pheasant's-eyes require for their well-being more moisture at their roots than other Daffodils. Therefore, on dry soils it is advisable to give them the moistest corner of the garden, and to take out no sunk alleys between the beds which contain them. Thirdly, and perhaps more important, the Pheasant's-eye ceases from growth for scarcely a week in the year, and cannot be said to have a resting-time for its bulbs. If there comes a dry hot spell of weather while it is in bloom, and heavy rain follows, it will commonly make long fresh roots before the leaves show signs of decay. In any case the bulbs will be found to have started into growth before the end of July. Accordingly, the variety *Ornatus* should be lifted in June, and the later variety of *Poeticus* as soon as the foliage turns yellow at the tips—not waiting for its more entire decay. And I advise that *Ornatus* be replanted before any other Daffodil. It is difficult to injure this robust plant seriously by any treatment, but for the best results let it be planted early.

With regard to existing kinds of *Narcissus poeticus*, the three best for ordinary purposes of cut bloom are *Ornatus*, *Recurvus* and the double *Gardenia*-flowered. A fourth, *N. poetarum*, is beautiful with its wholly red eye, but in many soils it is certainly not so robust as the others, nor nearly as floriferous as *Ornatus*, which blooms from quite small offsets, while *N. poetarum* blooms only from mature bulbs. The double kind is extremely beautiful when well grown, and most useful in filling a gap between spring and summer flowers. But it has the serious defect of producing a large proportion of empty or "blind" spathes. Many explanations have been given of this habit, and remedies propounded, but I believe no one has been able to conquer it. My own notion is that the plant has exceptional requirements in the way of abundant root-moisture, but that it demands also ample sun-heat at the same time to ripen its growth. This conjunction of conditions is not easily obtained, but it may be said that in open quarters, which have been deeply trenched and liberally manured at the bottom, there will be fewer blind spathes than on shallow hot soils.

Those who grow large collections of Daffodils may include some other Pheasant's-eyes in addition to the above-mentioned. *Angustifolius*, a slender-growing kind with narrow petals, is in most respects quite inferior to *Ornatus*, with which it blooms, but it possesses a singularly sweet and refined scent, approaching that of Sandal-wood. *Grandiflorus* is very large and striking, but increases so slowly that it is difficult to accumulate a stock. *Patellaris*, or the flat-crowned Pheasant's-eye,

is in all probability the single form of the well-known double *Poeticus*. It is the common wild *Poeticus* of the neighborhood of Montreux and other continental localities. *N. poeticus verus* of Linnæus, as it is called in catalogues, is a most beautiful kind, small in blossom, but with a circular flower of solid and overlapping petals. I consider it a most valuable kind for the hybridist, as likely to infuse substance and good shape into some of the larger sorts. Then there are small mountain varieties which are found in Italy, both north and south. That which has been catalogued as *Verbanus*, or *Verbanensis*, and takes this title from the Latin name of Lago Maggiore, is so abundant on some north Italian mountain-pastures that I have seen acres of it in one sheet, mingled with the blue *Gentianella*. It grows but a few inches in height, and seems to resent ordinary garden cultivation, but will live on the rockery or in grass.

Correspondence.

Impressions of America.—II.

To the Editor of GARDEN AND FOREST:

Sir,—Spring found me in one of the loveliest suburbs of Boston, bent on enjoyment of nature and study of this garden problem that exercises such a curious fascination on all who have once come under the charm. Houses and statues, books and pictures are all very well in their way, but their way is often a wearisome one. The conscientious art-critic, for example, is too often doomed to pass hours in the foul air of crowded rooms examining pictures by the hundred which ought never to have been painted. The garden-critic, on the other hand, has at least the solace of fresh air, and if he does sometimes feel that the flowers and shrubs he sees ought never to have been planted in that combination, flowers and shrubs are a good deal easier to re-arrange mentally than pigments. This re-arranging, indeed, gives a great part of the pleasure. If you cannot have really beautiful gardens with passages which at once stir the imagination into joyous activity by the sight of a broad, rolling, tree-flecked stretch of grass, with glimpses of a gleaming lake beyond set off by masses of *Rhododendrons*, just visible through a depression in the bluffs that hem in the water; or of English roseries, where music seems to float in the fragrance they exhale, and poetry is made visible in the grace and tenderness of their manifold forms; or of arching trellises, suggesting twilight meditation; or of such enchanting floral groups as are made when Tiger Lilies uplift their torches beside tall Irises robed in deep purple—if you cannot have pleasures such as these, at least you see floral beauty, even though it be misplaced, and your imagination will be kindled by the very mistakes and shortcomings you see. It is all so delightfully easy. Your imagination takes fire at the sight of a noble Lilac-bush crushed up against some coarse foliage in a stupid shrubbery, or a round bed of ill-assorted Geraniums lost in the grass, or a flat bed of nondescript color, from "assorted packets" of seed, at the foot of the piazza, or, perhaps, scraggly bands or beds of Tulips in the most trying combinations. You set to work at once setting the Lilac-bush free and making it grow full and round, as nature meant it, taking the Geraniums out of the bed, selecting one or two well-balanced tints of Pansies from among the "assorted" flowers, and filling the bed with them, while the Geraniums are variously distributed; the bright and scarlet and the frozen red ones are separated, put in with Ferns and Lilies-of-the-valley at the kitchen-door; the drooping specimens among the crimson-pink or white ones are planted with deep blue Lobelias and Ferns or Grasses in large pots or tubs, and put on the piazza-balustrade or placed as sentinels on either side of the front steps; the more upright Geraniums are used as a kind of support or setting to the house in the front border, along with Palms and *Dracænas* and other house-plants that want a summer outing, or among some of the perennials that have the right height and character. As for the Tulips, not one of the discordant ones is allowed to remain. It is all so delightfully easy—so much easier, indeed, to study it all out than to do it actually, and then have no end of care in the apparently simple task of keeping all intrusive tints away. Neither bulbs nor roots nor seeds are kind enough to wear the exact shade of red or purple or pink that their flowers put on in summer. It is the business of head-gardeners and nurserymen to know, though, and to provide their roots or seeds with unambiguous names, referring to a chart of colors, if one can be had, which will prevent their subordinates or customers from making painful mistakes.

The true garden-critic, however, is not hampered by any considerations such as these when in the full swing of re-

constructive fancy. Things grow and arrange themselves at his bidding, and out of a poor little suburban garden, struggling with dust and drought and want of pennies to spend on gardening, he creates a little bower of beauty. And, seriously, I do not think he is altogether so fantastic and unpractical as many people would make him out to be. Take the garden just alluded to, for instance. I admit that Lilac-bushes do not grow into the right shape in a night simply by being set free from contracted surroundings. But in most cases they will correct their own shape in time, and in gardening, as in other things, promise is often as pure a source of joy as fulfillment. You will observe that the other suggestions I made did not entail the laying of a single new bed, except one near the kitchen-door, and a bed of Lilies-of-the-valley and Ferns is not an expensive one. If you do not care to have that bed, you can always find some place to put the rejected Geraniums where their colors do not clash with those of other flowers. It is only a trifle more expensive to buy seeds—for the round bed—of one or two choice varieties of the same flower than it is to buy "assorted" packets. The bed running along the piazza can be managed by degrees. If you get one or two salient points to begin with—say the angles of the steps—the remainder will not disturb you so much, and you can go on gradually, getting nearer and nearer to your ideal till your bed comes fairly up to it, and you can turn your attention elsewhere. There are several cheap ways of filling such a bed as the one we are discussing, if you feel that you would like to keep it, and, by degrees, make it into an appropriate setting for the house to stand in. These beds are not so much the fashion now, and many people seem to hide their flowers carefully out of the way if they have any at all, and yet this flowery setting to the house may be easily made to have a consistent character and pleasing effect. There are many ways of keeping up this character; the one suggested above, of an artistic grouping of indoor plants that are kept over for next winter's use on either side of the piazza-steps, is quite effective, and might be made, with some knack in the grouping, to combine gracefully with the beginning of a herbaceous border. If there are no indoor plants available, and a herbaceous border is what you care most for, some of the perennials might be made to take their place, but, whatever you choose to have, do not let it look as if the piazza-steps were an accident cutting the flower-bed into two disjointed halves; let the flower-bed lead up to, and accentuate, the steps. This, again, can be done in many ways—everything can be done well in more ways than one, if you once set about looking for them. Again, if a herbaceous border be what you are aiming for, there is no reason for trying to convert the whole of the bed along the piazza into a herbaceous border at once; it can be planted bit by bit, filling in the ends with some such things as Mignonette or Poppies. The Mignonette would require a row of Nasturtiums or Scarlet Runners at the back to bind house and border together, and also some kind of a boundary line of Ferns or low Nasturtiums between them and the more elaborate arrangement near the piazza-steps. Either Mignonette or Poppies would allow of a border of Daffodils to make the house look bright in the spring-time.

As for the Tulips, the best plan is to start by buying the right ones; but, in any case, obnoxious ones can be weeded out either by making a little color chart when they are in full bloom, and marking the bulbs accordingly, or simply by tying something to the displeasing ones and discarding the bulbs when they are lifted. All this work of reconstruction is easier to plan than to accomplish, and yet it is much more satisfactory than criticising pictures, for you can continue at this for years and know nothing of art or beauty either. But you cannot begin criticising gardens without learning certain broad lessons in gardening, such as, for instance, that Hollyhocks do not bloom in the spring, and that different plants, in order to look well, must have different surroundings. From this it is only a step to begin to put your theories into practice, and it is this practice of gardening that deserves to be much more widely spread than it is. Gardening in America seems to me a luxury for the wealthy only, and there appears no good reason why this should be so. My first impressions of America in autumn had left me with a vague sense of perplexity at the inconsistency between the glorious woods and the uncared-for front-yards; my spring impressions only served to increase this perplexity. In a country where so much might be done, it is sad to see how comparatively little is done; how few of the residents in these Boston suburbs that I have had an opportunity of observing seem to appreciate the inestimable blessings of gardening as a fine art.

Milton, Mass.

Cealia Waern.

Is Spraying Overdone?

To the Editor of GARDEN AND FOREST:

Sir,—If Dr. Hoskins' opinion (p. 261) is correct,—“that we are doing more spraying in our orchards now than we shall do ten years hence,”—then it must follow that the work of our experimenters and the conclusions of orchard-owners are alike well-nigh valueless, for probably not one orchard-owner in fifty now sprays his trees. In comparatively few communities has spraying yet become sufficiently popular to exert any marked effect upon the fruit-markets, especially of the tree-fruits. Any diminution of this practice must reduce the value of the operation, so far as markets are concerned, to an insignificant margin. My own opinion is decidedly opposed to that of Dr. Hoskins. I am convinced that ten years hence three times more spraying will be done than now; and my faith rests less upon the present work of experimenters than upon the fact that very many of our most acute fruit-growers are ardent champions of spraying. I know of no recent practice in agricultural directions which finds so many earnest advocates among the best farmers as this; and this fact is indisputable proof of the excellence of the operation.

I am willing, and, in fact, anxious, to admit that much indiscriminate spraying is being done, and that some growers will be inclined to discontinue it; but this fact only brings out the more clearly the benefits which result from proper methods. It is also true that some of our insect and fungus invaders are occasionally our friends, but they are most unreliable friends. I cannot trust the codlin-moth to thin my apples; sometimes it thins them until none are left, and sometimes not enough. And if I breed a healthy crop of insects in the year when my fruit is abundant, I am afraid that I shall have too many of these helpers the coming year when my crop may be small. The codlin-moth and apple-scab are expensive allies. The only real benefit which I can get from them is the consolation that they will often ruin the crop of my neighbor who does not spray, and thereby leave the better market for myself who do spray!

It would certainly be effective treatment to “uproot every variety” of Apple which is subject to apple-scab, for then, in western New York, at least, we should have no market apples left, and we should have no occasion for spraying! But we cannot expect to convince our orchardists that it is wise to uproot the Baldwin orchards; they will at once answer that it is cheaper to spray. I own that we should attempt to produce scab-proof varieties, and Dr. Hoskins makes a good point in calling attention to the fact, but until we obtain them we must content ourselves with present varieties and carbonate of copper. We have no proof whatever that crosses with scab-proof varieties will give scab-proof offspring; and the means of obtaining such varieties are not yet known. There are, to be sure, many present varieties which are little affected by scab, but, unfortunately, most of them are not profitable market sorts.

We shall, no doubt, greatly cheapen and simplify the methods of spraying, but the practice, as a whole, is, in my opinion, one of the distinct advancements of modern times in agricultural and horticultural practice.

Cornell University.

L. H. Bailey.

A Good Example.

To the Editor of GARDEN AND FOREST:

Sir,—Last year the attention of your readers was called to the making of a semi-public water and wild garden by Mr. S. C. Nash at Clifton, New Jersey. It will be remembered that this had only recently been a swampy, worthless piece of ground, occupying a depression stretching along the public highway. The hollow had been fed by abundant springs, and nature had full sway for years to establish the various indigenous weeds, which, with the attendant animal life, make such places eyesores when near frequented roads, whose dust adds the last touch of desolation. Such places are only too frequent, and the attempt to convert such a waste into an orderly garden in keeping with the natural conditions of the situation seems so interesting that some report of the progress made may probably be encouraging and helpful to others.

Mr. Nash being an enthusiastic grower of aquatic plants, the first work done was the clearing out of the natural basins and adjusting the borders to which the waters should be confined. After clearing out the grasses and rushes it was found that the bottoms were covered with indigenous water weeds of no beauty, but of very rapid growth, which seemed an almost insuperable bar to further progress. These have been fought persistently for several years, but are still very vigorous,

and probably nothing less than a solid coating of sand as a smother will suppress them entirely. The wild growths which covered the sloping banks have been suppressed by the sand and mold which were used largely in regulating the grades. The upper reaches of the swamp have been regulated, but some of the attractive native growths of Cat-tails, bold Grasses, Arums, Azaleas, etc., have been cleared from encroaching and unattractive things, so as to leave bits of natural beauty in character with such a place. Among these, informal paths lead to quiet pools reflecting many a common and native plant which seem rare beauties in such a setting. The sloping grounds on the southern border have been somewhat cleared, and contain a multitude of Ferns, and are being gradually filled with hardy plants, placed quite informally among the sparse grasses and various creepers which now cover the ground. Some terrestrial Orchids, small Irises, etc., seemed quite in character here. But it is intended to make the water-garden the main attraction. The borders are now quite well filled with Irises (mostly *I. versicolor* and *I. Kämpferi*), *Eulalias*, Wild Rice, *Arundo Donax*, *Pontederia cordata* and *Calamus*. The main body of water is well stocked with hardy *Nymphæas*, of which there is a large variety. Some of the established plants were well in flower during my visit. The difficulty Mr. Nash experienced with his first plantings arose from the too abundant supply of cold water. This has been somewhat obviated, but the tender varieties are now grown in large basins formed by driving planks to confine the water, and in which it will become somewhat heated. The margins of these basins are masked by trailers and low-growing plants, while certain islets between them are devoted to grasses and plants with noble foliage.

Like all fanciers of aquatics, Mr. Nash has an ambition to flower *Victoria regia*, the giant of the *Nymphæaceæ*, and one of the wonders of the vegetable world. While this plant is flowered in this latitude in the open air, its growth is not entirely made there, and somewhat elaborate arrangements are necessary to bring it forward successfully. The plant, being an annual, is started from seed in strong heat, in January or early February, in the greenhouse and kept moving in warmth. As soon as the weather permits it is shifted into its permanent tank—one about thirty feet in diameter being necessary, and is covered with a tight frame with sash. It is necessary to keep the temperature of the tank at eighty degrees and upward and retain the covering until settled warm weather. The heat here was supplied by a stove, with water circulation sunk in a caisson alongside the tank. It is usual, I believe, to use the tank as the expansion tank of the stove, but here the tank was supplied with fresh water led from a greenhouse tank several hundred feet away which passed through the heater. The *Victoria* flowers in about four months from seed, the quickest-flowering being reported this season by Mr. Brydon of Yarmouthport, Mass., who had flowers in 107 days. Mr. Nash's plants will be in flower next month, and will probably be the only ones to be seen conveniently near New York City. The leaves of the *Victoria* are wonderful affairs, both in size and structurally. They are uncanny, fleshy-looking objects, but well worth a journey to see. It is a pleasure to be able to record the rapid progress of this park, which, while projected for private pleasure, is really a public improvement worth copying, especially where such waste places are prominent near traveled roads.

Elizabeth, N. J.

J. N. G.

Periodical Literature.

In *Harper's Magazine* for June there is an attractive article upon eastern Peru, written by Mr. Courtenay De Kalb, which shows how artistic, in its works of industrial art, a semi-savage race can be, and also how large a part the Palm-tree plays in these arts in the countries where it grows.

North-eastern Peru, which is called the Montaña, or "wooded country," has been brought more into contact with the outer world since the opening of the Amazon River to the traffic of all nations in 1866. But its white population, chiefly of Portuguese origin, has not yet "attempted entrance upon the domain of the arts." The landed proprietors, living in close association with troops of Indian agricultural laborers, have but sparingly introduced "the picturesque into their architecture, although the Portuguese type of structure, creeping up the river from Brazil, has feebly asserted itself as far as the materials at hand will allow," and the Spanish idea appears also in certain spots. "Here are the great porches and balconies, the open galleries letting a bit of light through the corner of the house, just under the red-tiled roof, and the pretty inner court, or patio, filled with tropical verdure." But "the pollen of Indian influence has modified exotic taste at times, where the

house resembles the Palm-thatched quincha, or native hut, and is decorated on the interior with Palm-leaf mats fastened upon the walls with the horizontally fluted Huicungo palm-posts at the doorways, and above them gratings of Palm-slats lashed together by vines, forming combinations of grace well worthy of imitation in other lands. Upon extraordinary occasions, when a dinner is to be given, they bring from the forests masses of the long green fronds of the Palm, vines all aflame with pink and scarlet blossoms, and the rich umbrella-shaped Paw-paw, and convert the banquet-room into a bower of fairy-like beauty."

As regards the minor arts, the writer says: "The common Indian is but a savage with some of the tricks of civilization, a house-builder, a planter of Maize and Yucca, a weaver of cloth and of hammocks, a fashioner of works of fictile art of surprising beauty. Without turn-table, simply by a feeling for correct form, are these jars, urns, dishes built up by hand with wooden spatulas. The decoration has become thoroughly conventionalized, crystallized, in fact, into a type of æsthetic expression which may truly be designated art. Predominant is the old classic form of fret and chevron, executed in subdued reds and deep browns upon a gray or creamy ground. Sometimes the leading design is in very heavy lines, with the ground filled in with an exquisitely delicate tracery of similar patterns. The plant-life of the forest is also reproduced—vines, not rudely delineated, but forming definite curves, springing upward at the end of the pattern and expanding into the calyx which holds the conventionalized type of a corolla, now a yellow five-rayed star, again a pink-flushed Lily's cup, or a sky-blue pendent bell. The artistic spirit displayed in these recalls the wonderful works of Inca art exhumed at the noted necropolis of Ancon. The Indian, again, manifests his appreciation of graceful form in the rounded ends of his quincha, which give an effective curve to the palm-thatched roof."

Recent Publications.

The third annual report of the Missouri Botanic Garden makes a handsome volume of one hundred and seventy pages and contains fifty-seven full-page plates. It contains the report of the President of the Board of Trustees, the director's report showing the progress of renovating the old garden and of extending and improving it, and telling of the development of the library and herbarium and of the school of botany, all of which, through the magnificent endowment of this establishment, are fast becoming of great importance and seem destined to make St. Louis the botanical headquarters of the New World.

Mr. Shaw, under his gift, has provided that a flower sermon should be preached annually in St. Louis and that the trustees of the Garden should give an annual banquet in honor of his memory, as well as a second banquet intended to bring persons interested commercially in plant-culture together. This volume contains the second of the annual flower sermons preached this last year by the Rev. Montgomery Schuyler, the proceedings at the second annual banquet which was given by the trustees on May 21st of last year at which the Secretary of the Interior was the guest of honor, and also the proceedings at the second annual banquet to gardeners, florists and nurserymen, given on the 10th of November.

Of more permanent interest to students of science are the scientific papers appended to the volume; these are Professor Trelease's *Revision of the American Species of Rumex*, occurring north of Mexico, to which mention has already been made in these columns, a paper by Professor Riley on the *Yucca Moth and Yucca Pollination*, also illustrated, and Professor Trelease's *Notes and Observations on the Genus Yucca*, which he has been engaged in studying in the field during the past winter. These notes are illustrated from sketches originally made by Dr. Engelmann, depicting the floral and capsular structure of several of the species which had never been adequately figured, which Professor Trelease had the happy idea to have redrawn in ink and then published by a process of photo-engraving. These sketches of Dr. Engelmann are supplemented by reproductions of photographs showing the habit and growth of several species which are here, in some cases, better portrayed than we have seen them elsewhere.

This volume, whose contents we have thus cursorily sketched, can be obtained at the cost of the publication (\$1.00) from A. E. Foote of Philadelphia, Wesley & Son of London, and of R. Friedländer & Sohn of Berlin; while applications for the purchase or exchange of either of the reports of the

Garden or of separate papers issued by its officers may be addressed to Professor William Trelease, the director at St. Louis.

Notes.

At a recent floral festival of the Linnæan Society of Jamaica, Long Island, one table contained seventy-five different varieties of wild plants in flower which were collected in the immediate vicinity, most of them rooted in pots. It was observed that this collection was the most attractive one in the exhibition, although the display of cultivated flowers was very showy.

A fortnight ago, New Hampshire's first state park was dedicated. This reservation consists of five acres of mountain-top on the elevation known as Pack Monadnock, in the southern part of the state. The elevation of the park is 2,385 feet, rising abruptly from the surrounding plains. The dome of the State House in Boston and the peak of Mount Washington are visible from the boulder which crowns the plateau. The land is the gift of private citizens.

No garden at this season is complete without the stately beauty of the Foxglove. Occasionally we see these plants massed together in a bed, but they lose nearly all their effectiveness in this way. They need to stand singly or in loose groups on the borders of a shrubbery or in some other place where their tall and graceful spires can be outlined against a green background. All of the colors through which they range are good, but a certain number of white ones are indispensable for the best effect.

Mr. Joseph Meehan writes us that in one of the open meadows at the National Cemetery in Arlington he recently noticed a specimen of *Quercus falcata* with a trunk measuring twelve feet in circumference. At about seven feet from the ground it branched into great limbs which reached out horizontally until they shaded a circle one hundred feet in diameter. There are many natural groves of White, Red and Black Oaks at Arlington. There are also some admirable evergreen Magnolias near the old dwelling and a good *Cryptomeria*; *Deodar Cedars* also thrive well here.

Zinc labels have been recommended for trees, and the prescribed practice has been to roll the labels simply around a branch, with the idea that as the wood grew the label would be expanded and the bark would not be cut. *Meehan's Monthly* says that this is an error, and asserts that the branch will grow over and around the label even when it simply rests on the upper part of the branch by its own weight. It is added that the only way to prevent any label or wire from growing into the bark of a tree is to attend to it every year or so and loosen it so that there is plenty of room for the wood cells to form.

In an article about Richard Jefferies, whose delightful books upon English rural scenes we have often quoted, a recent writer in *Literary Opinion* tells of a visit she had just paid to his parents who have been living for some years in Bath. She found his father, she says, "a healthy, good-looking man of seventy-five years of age, evidently the prototype of the Farmer Iden of 'Amaryllis,' and his mother a small woman of seventy-three, an invalid." They talked freely about "Dick," telling how he was always "sitting in the window, writing with a piece of pencil"; but they had read few of his books, had no conception of his fame in the world, and marveled much that for his sake they should be objects of interest to strangers.

In a late bulletin from the Agricultural Experiment Station, California, Professor Hilgard records some investigations made on prunes, apricots and peaches with a view to ascertain the proportion of pits to flesh, juice to flesh and sugar contents of the juice, and the flesh of different varieties. In regard to the nutritive value of certain fruits it has been stated in former bulletins that the orange in California rated the highest, but these researches give the apricot an equal rank, while the prune follows next, with grapes, bananas, apples and pears succeeding each other probably in the order named. Grapes stand first among the fruits in the quantity of mineral matter they take from the soil. The apricot, taken according to weight, holds the second place in this respect, while the prune and the orange come third.

In his recently published book, called, "With Poets and Players," in a chapter devoted to "Botany on the Boards," Mr. W. D. Adams says: "Great progress has been achieved of late years in the art of making stage trees and shrubs and flowers seem natural and convincing. In theatrical arboriculture in particular great strides have been taken. It is nothing

new to find the centre of the scene occupied by what, to all appearance, is a genuine tree, with real trunk, arms, leaves and blossoms. In these respects the stage mechanists of today can almost, if not quite, deceive the eye. . . . But such triumphs of the imitator's skill do but serve too often to show up in brilliant relief the unreality of the mock stone and wood surroundings in the way of house or fence. And too often, indeed usually, the stage-tree is only too obviously of the stage, stagey."

There are so many beautiful kinds of Lilies, each with a charm of its own, that it would be hardly just to single out one and pronounce it more beautiful than all the rest. But certainly it would be hard to name one that excels in good qualities the old-fashioned Ascension Lily (*Lilium candidum*), which has been cultivated probably as long as any other flower known in gardens. The disease which has injured it for some years past seems to have run its course; at least, these Lilies were never more luxuriant or the flowers more perfect than they have been this year. A mass of these flowers in full bloom, with some dark green foliage behind them, is a beautiful spectacle, and so is a group of them mixed with the tall blue spikes of the perennial *Delphiniums*. Hardy Lily-bulbs are usually planted in the autumn, but the bulbs of this one should be lifted in late July or early August and planted at once. At that time the stalks have died down, and soon after new roots begin to put out, and some glossy radical leaves spread over the ground and remain green all the winter. The bulbs should be planted before this new growth starts, or there will be a great loss in the vigor of the plant's growth.

The last number of *Forest Leaves* contains an interesting illustration, entitled, "A Historic Tree in Transit," and it represents a tree, seventy feet long and thirty-six inches in diameter, placed on a platform and moved along on rollers by block and tackle. The tree itself has a historic value, as it is an offshoot of the great Penn Treaty Elm which stood in Philadelphia. This tree measured twenty-four feet around the base, and one branch of it was one hundred and fifty feet long. It blew down in 1810, and a shoot which came up from the roots of the old tree was carried to the Oliver estate at Bay Ridge, New York, where it has stood for more than fifty years. This is the tree which was removed from there to the grounds of General Paul A. Oliver of Forest Roads, Oliver's Mills, Pa., whose ancestors owned the ground on the Delaware where the Treaty Elm stood. It was a bold undertaking to move so large a tree for 175 miles, especially since it had to be moved by horse and hand-power at the beginning and end of the route. General Oliver wrote on the 20th of June that the tree seems to be growing well and promises to thrive in its new home on the mountain-side as well as it did by New York Bay.

That portion of France which is called the Midi (the South), says Monsieur de Vilmoren, in his recently published book on *The Flowers of Paris*, includes all the territory lying south of Orange, and, consequently, the lower valley of the Rhone and the borders of the Mediterranean; but the term is more specially applied to the French portion of the Genoese coast between Hyères and Vintimille. This region is the great winter flower-garden of Paris, and, indeed, of a very large part of Europe. And its special adaptation to the winter cultivation of flowers is thus explained: "The peculiar climate depends upon several causes. In the first place, heat is persistent, as solar action is interfered with by clouds only one day in four. Then mildness is preserved in the valleys by the fact that they do not open directly upon the sea, but approach it obliquely; and thus, of course, the hills which lie between them and the sea are well exposed to the south and offer very favorable locations for plants which require a great deal of heat. This disposition of valleys and hills protects them almost completely against the cold winds of the north, and especially against the mistral, which, a little farther northward, destroys all delicate plants. On the other hand, the wind which blows from the sea, bringing with it the warmth of the African shore, finds no obstacle, and the immediate vicinity of the sea always equalizes the temperature of a country. . . . A particular characteristic of cultivation in the Midi," adds the author, "is the great use made of protective coverings; for the same reasons which cause the great heat of the day also produce great chilliness at night. The sky always being very pure, nothing opposes the radiation of the soil and its plants, and, therefore, these last have always been covered by coarse mats of reeds, which may also serve to protect delicate flowers from the burning rays of the sun. Recently, however, glazed sashes have come into use, and are now almost universally employed instead of the mats, being heated, except in rare instances, by nothing save the rays of the sun itself."

Simplicity in Landscape-art.

ONE thing that used to strike the traveler in Europe with a sense of novelty was the look of cultivation about the railway-stations, and few things in this country bear greater evidence of the advance in civilization among us than the improved aspect of these public thoroughfares. In fact, everywhere in the east we are conscious that the air of raw newness, of uncombed carelessness, is beginning to yield to the demand for order and comeliness of arrangements. The idea that system may be applied to even very limited portions of ground is gradually making way, and people are beginning to consider not so much what they shall plant as how they shall plant it so as to produce the best effect.

There is a taste for beauty latent among our people which thirsts for guidance, and only needs good examples to develop it properly. They eagerly seize upon such advantages of instruction as are afforded, and show their desire for new light in various ways. The village improvement societies are a step in the right direction, and the well-kept door-yards in small New England towns, the trig and thrifty air that pervades even the humblest homes, show that there, at least, the new ideas have taken root, and are ready for evolution. What is most needed now is to train and educate this love of the beautiful and befitting, by setting authoritatively before the public evidences of the right way to produce good effects in the management of trees and shrubbery, and to make public resorts serve to emphasize the important truths of simplicity and unity in design.

We do not have the advantage here of free access to the gardens and parks of royalty and nobility, as European peoples do, to educate our understanding. Such examples as the public has had in old times to copy have not always been of the best. There have been no great gardens like those of Versailles and of Luxembourg thrown open to

everybody on festival days; it is only within the last twenty-five years that carefully planned parks have been accessible to the million, and that cities have decorated their pleasure-grounds with shrubs and flowers. How eagerly the people seize upon these advantages, how jealously they guard their rights to them we all know; but not every one recognizes the educational value of these well-kept open spaces, nor do we perhaps grasp the full force of the refining effect that the contemplation of good landscape-gardening has upon the minds of the masses, who are imperceptibly led by it to understand the value of composition in the arrangement of growing things, and thus are taught a lesson in beauty.

To love beauty is far easier than to know what beauty is. The most beautiful things are not, as many people think, within easy grasp of the understanding. Beauty of an unfamiliar kind does not always seem beauty at the first glance. It has to educate us to understand it, open our minds to its preciousness, and lift us to the higher level of its charm before we begin to recognize it. The Hermes and Aphrodite of the Greek mean nothing to the Australian black fellow, nor do they appeal profoundly to any untrained intelligence, for perfection in the human form is unfamiliar to the average eye, accustomed to look alone upon the face for beauty, with its ideas of figure outline warped by the conventionalities of fashion.

The greatest objects in nature—even Niagara itself—is disappointing to the visitor until he has dwelt for a space upon its borders, and has learned the full terror of its majesty. Day by day the torrent grows more imposing, its ceaseless roar more impressive, the sweep of foaming water more turbulent, the crisis of the great fall more tremendous. It is so with the glories of a mountain-region. One's first glimpse of the Alps may be awe-inspiring or commonplace, according to the atmosphere, but it is only a long sojourn among mighty hills that fully reveals the power they possess over the soul of man. No superficial view can reveal their secret. Alone with the humming of bees amid the Alpine roses, with snowy peaks upon peaks rising needle-like against the blue, and lonely eagles soaring slowly into the upper ether, one feels a stirring within him as of wings, and becomes conscious of that inward bursting of bonds which denotes mental growth. Then the mountain speaks to man, and the favored mortal learns a new lesson of beauty.

The truth, well established in literature, art and music, that any new departure has to create a taste for itself before it can be accepted, is equally recognizable in landscape-gardening, which may justly be ranked among the higher arts, since he who takes nature for his theme uses trees and flowers for his pigments, and is the greatest of all painters. What seems the easiest, and yet is perhaps the hardest to learn of all, is the lesson of simplicity. To accumulate is the natural instinct of man; to overcrowd both house and land; and yet neither within nor without does quantity produce quality, and the higher one's artistic sense develops, the more does he value space as an element of dignity and loveliness. The true value of a picture is best obtained when it hangs alone upon a wall. The beauty of a precious vase is lost in the confusion of a cabinet. The Venus of Milo, standing solitary in her curtained alcove in the Louvre, is more impressive than the gallery of other Venuses which leads up to her shrine. So may one obtain the strongest effect for a group of trees, or for one giant specimen considered by itself, if they are left to stand alone, in one great sweep of lawn, which shall emphasize by contrast every noble curve, every up-lifted bough, and produce one salient point in a lovely picture.

A mass of foliage in a shrubbery, forming one continuous and graceful line of varied shades of green, interspersed with sprays of blossom, is finer than a spotted effect of numerous isolated bushes, however beautiful in themselves. A group of plants in a garden all of one kind is usually better than a mixture of different plants. A

pleasance should ever be a picture, and be treated with the same artistic care, not to spoil its unity or to muddle its lights and shadows, that the painter should show when dealing with his canvas. Tone, gradation, emphasis are as important in the garden as in the drawing. There should be a high light, a depth of darkness—a middle distance, a foreground and a perspective. This, as the Japanese show us, can be managed even in a tiny enclosure; but what the average gardener lacks is courage to destroy. It is only a master in landscape-construction who dares to cut a swathe through a forest, or fell a giant to improve a vista. Such a destroyer, as we have shown before, is looked upon with terror by the uninstructed, when he demands the sacrifice of some long-cherished Oak or Pine which has been an object of family pride for years. The flower-beds have always been in one spot, why should they be disturbed? A grandfather planted that Chestnut; there is a sentiment against cutting it down. It is obstructions of this kind that are encountered by him whose far-seeing eye looks into the future, sees the perfected picture with all its detail subordinate to one leading thought, and grows impatient at what seems to him irrelevant obstruction.

The first lesson of beauty, then, to be learned by the student is the lesson of simplicity and breadth. To this he must come by the hard road of sacrifice, giving up many a cherished prejudice, many an object long unwisely valued. When he has grasped this idea as of preëminent value, he will have made the first step in a true knowledge of the requirements of landscape-gardening as an art, and will have permanently mastered an elemental truth with regard to all artistic beauty.

A Bit of Wild Nature in Pennsylvania.

THE "Bear Meadows," in Centre County, Pennsylvania, have long enjoyed a local reputation among lovers of nature as one of those odd places so different from its surroundings as to excite great curiosity. It is simply a peat-bog, occupying, perhaps, a mile square of what, if the drainage and water-flow were better, would be a "kettle," in the hunters' vernacular. The surrounding ridges, though low, are ample enough to give a small, but very constant, stream, the outlet of which being impeded holds back the water, once, perhaps, as a small lake, but now silted and choked with peat, through which the sluggish dark-colored water slowly forces its way.

Such a bog, in a region where bogs and lakes are uncommon, almost unknown, has naturally been a marked spot in the topography of the neighborhood and a favorite and attractive place for hunting and fishing. To a naturalist the chief attraction is in the curious commingling of the flora. The centre is covered almost exclusively with the commoner and coarser Sedges, with here and there clumps of Alders and occasionally Cranberries. The peat is here over ten feet deep, and shakes perceptibly under the tread. The larger area, however, is the border of the marsh, over which is a vigorous growth of a great variety of trees, in marked contrast to the meagre selection afforded by the surrounding higher lands. Many species, too, have acquired unusual size, and though culled out more or less, the general effect is of the "forest primeval." Huge White Pines, Tulip Poplars and Red Maples are frequent. Black Spruces abound in certain places, and reach large dimensions, their dark spiry tops making a skyline in sharp contrast with the other trees. In much smaller numbers, and seldom more than a foot in diameter, are the Balsam Firs. Locally, both species are called Tamarack, a curious misnomer, the occasion for which I have not been able to discover. Their small slender trunks have always been in great demand for flag-poles, hay-ladders, etc., and but few would have been left had the meadows been more accessible.

Of minor plants there are many to attract the visitor. Probably to most persons the Pitcher-plants are the most curious, since they grow nowhere else in the neighborhood. Bedded in the Sphagnum-moss they are perfectly at home, and grow vigorously. Gold-thread, the Painted Trillium and the Buckbean (*Menyanthes*) are other characteristic marsh-plants of the north that are here. The latter seems quite out of its latitude. It is not abundant, and does not seem to be holding its own. In places the round-leaved Sundew is abundant, and so are the delicate little Star-flower (*Trientalis*) and the dwarf

Cornel. The smaller *Smilacinas* and *Clintonia borealis* are frequent and very vigorous, and their symmetrical polished green leaves at once attract attention. Orchids are naturally sought for in such a place. Some are quite common, such as *Cypripedium acaule* and *Habenaria ciliaris*, both running up and into the drier ground, and often quite striking because of their abundance. Less commonly met with are *H. tridentata*, *Listera cordata*, *Pogonia verticillata* and *Calopogon pulchellus*. Still others would doubtless reward a careful search were one to take time at the proper season for them. It is slow and tiresome work to explore the tangled parts of the border and the drier hummocks. The thickets of *Rhododendron* are exceedingly dense, and when mixed with the common Green-brier (*Smilax*) are scarcely penetrable.

In these thickets were made the bear traps or pens, from which the name Bear Meadows is derived. In days gone by this was the great fascination the meadows had for the hunting fraternity. At some one of the numerous springs about the border was the favorite place to camp. Cooler, more soft and delicious water than came from these sand-stone springs nowhere existed, while the charm of a summer-night here under the stars was indescribable. Nowhere else did the air seem so balmy and invigorating, and that exquisite music, the sighing of the Pines, was seldom wanting.

About three years ago, in writing to *Forest Leaves*, I said that a lumber company had recently begun work hereabout, were building a tramway with which to reach the meadows, and were preparing to cut, as they expressed it, "everything down to the size of a stove-pipe." Thus far they have been cutting chiefly the Pitch Pine, which goes to the anthracite region for mine-supports or "prop," as it is called. They have now begun to penetrate the meadows, have put up a mill, and are sawing the larger timber. The best of the White Pine is cut up into bridge material, the poorer and refuse parts into shingles, pickets, etc., while the Spruce and Fir, so far, all goes to the pulp-mills. The illustration (page 319) shows one of the White Pines which have been felled, and gives the imagination an opportunity to picture the changes which a band of energetic choppers are likely to bring about after they have worked their will in a forest. The ground is more marshy here than the picture indicates. The tramway rests on slabs to keep it from settling, and horses are preferred to mules, because the smaller hoofs of the mules sink more easily in the soft footing.

The fear that fire would follow in their wake has in part been realized. Last year was the worst for many years, while this season there have been no fires at all.

Considering the marshy nature of the meadows themselves, it may be that even after being thoroughly worked over and littered with tops and rubbish, the swamp may escape a general conflagration. This would be fortunate, for, left again to Nature's tender care, it would in time be re clothed and renewed, and be, perhaps, to another generation what it has been to this—a place of unspeakable restfulness. Nature has here been left alone to do her perfect work, and the Bear Meadows are so closely walled in by mountain-ridges that the busy work-day world seems hundreds of miles away.

State College, Pa.

W. A. Buckhout.

A Manufactory of Roses.

THE following translation of an article by M. Henry de Vilmorin, in *La Revue Horticole*, appeared in a recent number of the *Literary Digest*:

I have several times had occasion to visit the famous Park of Roses, at Nice. The flowers produced there are the most beautiful in the world.

Both banks of the Var are bordered by a line of hills of some height, which are prolonged as far as the sea. The hills on the left bank aid in protecting the whole plain of Nice from the north-west wind. Toward the southern extremity of these hills, on very rich, alluvial soil, is the Carras quarter, in which are the principal market gardens of Nice. In that quarter, also, a little higher up on the slope of the hill, is the Josephine Villa, or Park of Roses.

Here roses are cultivated exclusively for sale in winter as cut flowers. Out of the twenty-eight or thirty acres which the property comprises, about ten acres are devoted to the purpose of forcing the Rose-trees, and are covered with very numerous small greenhouses or extensive hot-bed frames, one or the other of these being always in use for furthering the production of the flowers. The total surface covered with glass exceeds 6,000 square metres, or an acre and a half.

Naturally, it is during the months of active sale, from

November to April, that the principal harvest occurs; but even in the spring and summer the very beautiful roses grown under shelter are in demand by the dealers. These roses are the only ones, or nearly the only ones, which show a purity of perfect tint, exempt on the outside petals from the discoloration, the veining and folds, which are caused by the bite of cold, too warm sun-strokes, or the prolonged action of humidity.

During the summer the movable sides of the greenhouses are taken away, and there remains only the glass roof which protects the flowers from the rain-storms.

The proprietor and founder of the establishment is Mr. Antoine Mari. It may be said that the most striking feature of his mode of cultivation is the simplicity of the means employed and their perfect adaptation to the end to be attained, which is to obtain an abundant and continued production of flowers without great expense and without exhausting the plants.

A Rose-bush, as is known, does not require a high temperature. Certain varieties, like the Saffron Rose, continue to put forth buds and flowers all winter long in Provence, and well-developed roses of that variety can be picked at the end of November even in the climate of Paris. At Mr. Mari's place the Rose-trees are planted either in three lines, parallel to each other, for the bushy variety, or, in the case of those with flexible stalks, each by itself, something like Grape-vines, as, for instance, the Marshal Niel. They are sheltered by frames just high enough above the ground to allow of man walking about inside. At the height of the season, from December 15th to April 15th, the Park of Roses sends away an average of five hundred dozen roses a day.

At the last Floral Exposition at Nice I had an opportunity to admire the choicest products of Mr. Mari's establishment. There were Paul Neyron Roses more than twelve centimetres (four and three-fourths inches) in diameter; Marshal Niels so enlarged that a dozen buds half-opened weighed together more than eight hundred grammes (1.76 pounds avoirdupois), some La France Roses of a marvelous size and symmetry, and some Paul Nabonnands, nearly as large as the Paul Neyrons, and of a deliciously fresh color. All the roses, without exception, had a perfection of form and a brightness of tint which left nothing to be desired. It is no secret that a large proportion of the most beautiful roses in the most elegant flower-shops in Paris come in a direct line from those cultivated by Mr. Mari.

The Park of Roses brings to its proprietor a net annual revenue of 10,000 or 12,000 francs for every two and one-half acres of land.

Late June in the Garden.

I HAVE been wishing for an artist's skill to portray the pretty picture that greeted my eyes the other day when I peeped into a Yucca bell. They were not fairies, the dainty occupants, but they were as pretty as fairies, although they took the shape of pure white moths less than an inch long, who had fancied the Yucca's spotless cool interior for a noon-day nap. There were at least a dozen of them. I looked into other bells on other Yuccas and found them occupied by the same airy visitants. Are these the Yucca moths whose mission is to fertilize these beautiful blossoms, and thus to pay for bed and board? A heavy thunder-shower came up; the Yuccas swayed in the wind, bent over until they swept the ground, and the blossom seemed too frail a tenement to sustain its occupants. I felt sure that they would be dislodged and blown about at the mercy of the elements. The rain fell in sheets, and when the storm was over I peeped again into the dripping bells. Not a moth guest was discomposed; all seemed to sleep serenely, waiting for the fire-fly signals that should herald the summer-night and awaken them to elf-like revels under the mighty Oaks.

Nothing can be more beautiful than the night aspect of the immense clusters of Yuccas, some of them planted forty years ago, which are now blooming in many places in the old garden, holding up tall candelabra to be filled with moonlight, which they catch in every chalice of pearl. Some of the flower-stalks are seven and eight feet in height. The first to bloom was *Y. filamentosa*, variety *flaccida*. Several varieties planted last year, such as *Y. superba*, *Y. angustifolia* and *Y. recurva*, have not yet bloomed, but are making satisfactory growth. These crown a little hillock north of the house, in company with some *Rhododendrons*, *Aucubas*, *Laurels* and *Arundo donax*. With all of these they combine effectively. They seem to rather enjoy drought and neglect, and thrive well when left to themselves, but are very easy to transplant and hard to kill. I have seen them rooted and blooming happily on top of an old rubbish-heap where they had been thrown to die.

The common name for this plant hereabout is Cliff-lily. I do not know why it is so called, unless it be that it prefers hilly ground in its wild state. Several years ago, when I knew the botanical names of very few plants, I was led by the enticing descriptions and beautiful illustrations—which I did not recognize—in the catalogues to send for a few roots of *Yucca filamentosa*, and was as much chagrined as surprised to find when they came that they were the familiar Cliff-lilies with which the garden was already overstocked.

Trumpet Creeper (*Tecoma radicans*) is flaunting its orange-scarlet blossoms everywhere. It has subjugated the old paling-fence and converted it into a most luxuriant hedge, and it scoffs at all control and riots over the beds and up the shrubs and trees, peeps out in most unexpected places and keeps one busy all summer long in the vain effort to reduce it to submission. Now it is detected in the act of strangling a promising young fruit-tree, again it is quarreling with the Clematises for the possession of a trellis; it has taken all the best places in the Honeysuckle-arbor, and conquered a rock-brake under the Cherry-trees north-east of the house, which it beautifies in its own wild fashion, and where it is quite welcome to twist and twine and luxuriate at will.

Very large clumps of Hollyhocks of white, yellow, rose, red and wine-colored shades are still blooming. One of these clumps in front of the carriage-house seems most appropriately placed. There is a suggestion of homeliness about this flower, in spite of its stately beauty, which makes it fit such a situation best. Farther down the grove, in too close proximity to the Oaks and other forest-trees, it would seem misplaced, but in the neighborhood of buildings and in fence-corners and garden-borders it is perfectly at home.

Many *Spiræas* are now blooming. Among the prettiest of these is *S. Bumalda*, which is a *Spiræa* of small size, growing rapidly to maturity in good soil, and producing its pretty clusters of pink blossoms all summer long. It is grouped with the white variety, *S. callosa*, and the pink and white flowers of these two *Spiræas* mingle very pleasingly.

S. sorbifolia is just coming into flower, and is a large bush of rapid growth, handsome white flowers and beautiful Mountain Ash-like foliage. It is planted in company with *S. Lindleyana*, which has not yet blossomed at Rose Brake. This latter has somewhat similar foliage, seems quite hardy here, but does not grow very fast.

S. callosa is now very pretty, with large clusters of bright pink showy flowers, and *S. Billardii* is a great bush, covered with spikes of rosy bloom, very ugly when they fade, and requiring much attention from the garden-scissors to keep it presentable.

Privets are flowering, and a pretty little *Cytisus*, labeled *C. capitatus*, is giving a few heads of bright yellow blossoms, which are slightly fragrant. *Ceanothus Americanus*, or New Jersey Tea, is a neat little shrub with numerous clusters of tiny white flowers, very much resorted to by little, round, shiny black rose-bugs, dainty little epicures, which seem to prefer all our prettiest flowers. They are very troublesome to the Ramanas Roses, which are still in bloom, and they eat the blossoms of the pink-flowering Raspberry (*Rubus odoratus*), whose boasted fragrance I am unable to detect, although I am, perhaps, unusually sensitive to the perfume of flowers.

At this season the *Polyantha*, or Fairy Roses, flower very profusely. Indeed, they never stop blooming until checked by hard frosts. The hybrid Clematises, though some of them are less interesting than the species, are giving abundant flowers of various colors, and the pure Madonna Lilies, which are very beautiful in a large cluster on the lawn.

The meadows are gay with white, purple and pink Larkspurs, with Milkweed, white and yellow Daisies, the blue flowers of the Viper's Bugloss, and many other sturdy plants. Here and there an orange-colored patch of *Asclepias tuberosa* delights the eye; neglected orchards are overrun with Wild Mustard, and Elder-blossoms are still whitening the hedge-rows and corners of the pasture-fields with late wild Roses in loving companionship.

Rose Brake, W. Va.

Danske Dandridge.

The Mutual Influence of the Stock and the Graft.

IN the report of the Michigan Horticultural Society for 1891 Mr. A. A. Crozier has a most instructive paper on this subject. He collects together most of the opinions which have been published, together with the evidence upon which these opinions are based. As a rule, the observations here put on record have not been based on direct experiment undertaken for the particular purpose of determining the modifying influence of either the stock or

the graft. Many of the statements are contradictory, and much of the testimony has to be rejected. Some of the changes said to have been observed are plainly imaginary, and Mr. Crozier has allowed them to appear simply to show what beliefs have been held. Careful and well-directed experiment will, of course, be necessary before the points involved are settled, and we are pleased to observe that Mr. Crozier himself promises to conduct some of these trials. But, although this evidence reported is not all of very serious value, there are altogether forty pages of quotations published, and a careful examination of them gives abundant proof that both stock and graft do influence each other's growth in very many ways, and Mr. Crozier gives the following conclusions which he has deduced from a careful study of the existing evidence :

SIZE AND VIGOR.—The stock and graft each imparts to the other something of its own degree of vigor or lack of vigor. This influence is greater the first year or two than afterward. If the difference in vigor is great, both stock and graft may ultimately perish. The dwarfing which in certain cases results from grafting does not always arise from a diminished supply of food, but often indirectly from earlier and more abundant fruitfulness.

FORM.—The alterations in the forms of trees, as the result of grafting, arise mainly from increased or diminished vigor. This probably applies also to alterations in the form of the roots, vigorous roots having larger, longer and fewer branches than feeble ones. Many of the observed changes, however, in the form of the roots of grafted trees, are probably due to the trees having rooted from the graft. The observed changes in the form of the fruit of the graft, causing it to resemble that of the stock, are as yet too few to be considered other than accidental.

FRUITFULNESS.—The most important of all the results of grafting is increased fruitfulness. This is brought about (1) by the mere process of grafting, which operates in the same manner as a ligature; or the removal of a ring of bark; (2) by diminished vigor through defective nourishment from a feeble stock; (3) by increased vigor imparted by vigorous stocks to varieties which are naturally too feeble to bear heavily.

PRECOCITY.—Earlier, as well as more abundant, fruiting is induced by the act of grafting; also by diminished vigor due to dwarf or feeble stocks. The precocity of trees on dwarf stocks is not, however, always directly due to diminished vigor, but largely to the habit of early bearing imparted to the graft by the stock in a manner not fully understood. Probably the diminished supply of sap derived from dwarf or feeble stocks, and its consequent richer character, is an important factor in inducing the earlier and more abundant fruitfulness.

SEASON OF GROWTH AND MATURITY.—The stock and the graft each modifies the period of vegetation of the other when their normal times of beginning or closing their season's growth are different. Thus, a late variety grafted upon an early stock begins and ends its season's growth earlier than it otherwise would. This alteration in habit appears in some cases to affect the time of ripening of the fruit.

HARDINESS.—There is some evidence that hardy stocks increase the hardiness of the grafts. This, however, does not appear to be by the transfer of any inherent hardiness peculiar to the variety, but to result from the increased or diminished vigor in certain cases or an earlier maturity in varieties which, upon their own roots, are inclined to grow too late in the season. The advantage usually sought in hardy stocks is to furnish hardy stems able to resist injury to the bark by sun-scald, etc., and to supply roots of uniform hardiness in place of those of ordinary seedlings which are frequently less hardy than those of most cultivated varieties. Conversely, a hardy graft has been known to increase the hardiness of the stock, but known examples of this are rare, and usually no such influence can be observed.

ADAPTATION TO SOIL.—“Favored by the influence of the stock, many species are able to thrive in unfavorable soils, and often in those in which they could not live if upon their own roots.” There is in this fact no evidence that the character of either stock or graft is modified. In some cases, however, the demands of a vigorous or fruitful graft may render the roots of the stock more exacting as to soil, so that they require one which is more fertile or of more definite character in which to maintain in health the grafted tree than would be required for a tree of the same kind as the stock growing in its natural state.

COLOR.—An alteration in color, as the result of grafting, may occur (1) by the direct transfer of coloring matter, as in the ex-

ample of the white and yellow carrots; (2) by earlier or later maturity; earlier maturity inducing more heightened color; (3) by the restoration of normal nutrition to a “variegated” stock or cion; (4) by the transfer to a healthy stock of the disease known as variegation. There is little evidence that the characteristic color of fruits is modified by grafting.

FLAVOR.—The testimony is abundant that fruits may acquire the flavor of the fruit of the stocks on which they are grafted; this has been especially noticed in the case of sour Apples grafted upon sweet varieties. Other modifications in the flavor and texture of the fruit have been noticed which do not cause them to resemble the fruits of the stock. The operation of grafting itself often causes the fruit to be larger and more succulent, and to ripen earlier; this latter change, when it causes more perfect ripening, improves the flavor. We can say that certain stocks improve the flavor of fruit borne by the graft, while others deteriorate it, and that it is probable that stocks bearing highly flavored fruits intensify the flavor of the fruit borne by the graft, while stocks bearing fruits which are sweet or mild in quality diminish it; but, notwithstanding the abundant testimony to this end, direct and careful experiments are needed.

DISEASE.—The evidence is conclusive that certain diseases may be conveyed from stock to graft, and vice versa. This applies not only to diseases caused by parasitic fungi, but also to the peculiar form of malnutrition known as variegation. It will be observed that nearly all the best-established changes which are noted are due to altered nutrition, and though they sometimes cause the stock and graft each to acquire some of the features of the other, these alterations extend mainly to such points as vigor, color and period of vegetation, and in no case can they be considered to be of the nature of hybridism.

Fruit Trees in Flower.

I AM advised by friends to cut down a huge Pound Sweet Apple-tree which stands among the shade-trees on my lawn, but in my judgment none of the rare and beautiful trees which are called ornamentals surpass this one when in flower with its exquisite shades of white and red. The love of the Japanese for Plum and Cherry-trees amounts to a passion and almost a worship, and this, not because of their fruit, but of their flowers. During the season of apple-blossoms I have driven about the country a great deal and made notes of some remarkable developments of high-colored flowers in certain individual trees. I found one growing near the roadside with flowers of a fairly dark purplish red, a tint I have never seen before. Another tree I have found which bears blossoms closely approaching scarlet in color. My purpose is to secure cions of these trees and have them grafted next spring, for as flowers they deserve to rank among our richest. Certainly it is worth while to collect examples of such variations so that we can see apple-blossoms carried through their widest range of color.

The Peach is always beautiful in flower, but occasionally some individual tree is almost startling in its attractiveness. The rule seems to be that the finer sorts of Peaches have less conspicuous bloom. The very handsomest trees in flower are the wild ones along the wayside in Kentucky, Missouri and Arkansas. Some of these ought to be selected and treated purely as flowering trees. Cherries, so far as I know, do not have blossoms which sport into colors, but a Morello is sufficiently attractive in white. It is a complete globe of flowers and small enough to occupy a place in an ordinary shrubbery. Then, too, it has a capacity for blooming when very young, and a tree three years old will burst into a miniature flower-garden three or four feet in diameter.

Pear-trees appeal to us for the beauty of their foliage as well as their flowers. This is the one fruit tree with rich glossy leaves, and sometimes it has a noble and unique habit, while in the autumn it gives us unsurpassed colors of foliage. The Buffam is one of the best trees to plant where a fastigate form is needed, and it is unrivaled for the crimson and purple of its October foliage, besides which it is a delightful tree in bloom. Some of my own trees, twenty feet high and no more than six or seven feet in diameter, form a pyramid or sugar-loaf of perfect white in flower. Of course the flowers of all these trees are evanescent, but so are those of most other flowering trees and shrubs, and certainly in planting trees for the beauty of their flowers these fruit trees should not be entirely neglected.

Indeed, the whole family of Rosaceæ is eminent for the freedom with which they yield delicate flowers. Some sorts of Strawberries can be used very effectively as edgings, and after the bloom is over the show of fruit is very pleasant to

the eye, especially on such plants as carry it well up out of the dirt but on stalks not too long. Such varieties as Haverland, for example, are not useful for this purpose, but Cumberland is excellent, and among some cross-bred varieties I have one with semi-double flowers which is most interesting to look at. Dewberries are admirable screens, and so are the so-called Wine Berry and our native Thimble Berry.

There are few shrubs which can rival the beauty of a Quince-tree in full bloom. On the first of June I had a small orchard of forty of these trees covered with flowers, and it was a superb spectacle. I grew a few of them in my shrubbery for the sake of the flowers alone, although the pale

flower, is always a delight to the eye. There are few finer shrubs than the dwarf Apples, and both the Apples and Cherries can be managed very readily in this way.

Clinton, N. Y.

E. P. Powell.

New or Little-known Plants.

Jacobinia magnifica.

THIS is a useful greenhouse-plant which formerly was commonly grown in English gardens, but is comparatively rare here now. Like most of the *Acanthaceæ*,

Fig. 56.—*Jacobinia magnifica*.

downy leaves have a value in a landscape. The flowers are equal in beauty to those of the *Stuartia* or an *Exochorda*.

Again, most of our fruit trees are as beautiful in fruit as they are in flower. To my imagination there is not a more beautiful object than a large Snow Apple-tree in October. I always dislike to pick off Jonathan apples from the tree, they are so beautiful as they hang upon the branches. What more beautiful picture can be seen than a Morello or Richmond Cherry-tree just as the fruit is turning crimson. I have said nothing of the value of dwarf trees for lawn-planting because many persons make a failure when they attempt to grow handsome trees in this way. Such failure is not necessary, however, and a dwarf Richmond Cherry, either in fruit or

it is either a scraggy weed or a handsome little shrub, according as it gets bad or good treatment. At Kew it is grown in quantity for the conservatory, flowering with a rush in November or December. It is raised every year from cuttings struck in heat in March and grown on in a warm moist house until July. The plants are by this time in six-inch pots, in which they remain until they have flowered. They like a rich open soil, such as suits *Begonias*, and plenty of water. From July onward the plants are placed in a frame where they get plenty of sunlight and air, the lights being removed on all favorable occasions.

By November they have formed compact little shrubs (they are stopped twice), leafy to the top, and from a foot to one and a half feet high.

The stems are quadrangular, the leaves opposite, lanceolate, wavy, with prominent veins and covered with a soft down-like tomentum. The largest leaves are nearly a foot long by three inches in width, but the bulk of the leaves are only about half that size.

The flowers, which are a rich rose-purple color, are arranged in dense terminal heads, as shown in the picture, which has been prepared from a Kew plant. The old plants—that is, those that flowered last December, and a few which were preserved for the supply of cuttings—are now flowering again. There are several varieties of this *Jacobinia* in cultivation, namely, *J. magnifica*, var. *carnea*, figured in the *Botanical Magazine*, t. 3382, as *Justicia carnea*, and which, according to Lindley, was sent from Rio to the Royal Horticultural Society in 1827. This has glabrous leaves and flesh-colored flowers. The variety called *Pohlina* is, I think, so widely distinct from what is here figured as to deserve specific rank. It has ovate-acuminate leaves, almost cordate at the base, thin in texture, quite glabrous and tinged with purple beneath.

The flowers are bright crimson in color, and they differ in other particulars from those of *J. magnifica*. It was formerly called *Cyrtanthera Pohlina*, under which name it is still known here and there.

Other species of *Jacobinia* similar in habit to that here figured, and well worth growing for their handsome flowers, are *J. aurantiaca*, introduced by Makoy & Co., of Liege, Belgium, in 1849, who distributed it as *Calcostylis aurantiaca*. It has four-angled stems, lanceolate smooth leaves and large terminal heads of yellow and orange flowers. Another handsome yellow-flowered species is *J. catalpæfolia*, which has large cordate leaves and flowers arranged in terminal heads six inches long and four inches through.

J. coccinea flowers in summer. It has rather rigid cylindrical branches and lanceolate leaves, with heads of crimson flowers. It is sometimes met with under the name of *Aphelandra cristata*.

According to the *Genera Plantarum*, there are about thirty species of *Jacobinia*, all natives of tropical America. The genus now includes *Cyrtanthera*, *Libonia* and *Sericographis*.

London.

W. W.

Gladiolus Armeniacus.

THE numerous showy hybrid Gladioli have so far superseded the species in cultivation that, with few exceptions, one seldom sees any of the Cape or Asiatic species. There are very many of these, and among them a number of interesting things, but practically of little garden value in comparison with the hybrids of the florists. One of the newer species from Herr Max Leichtlin is *Gladiolus Armeniacus*. This has proved with me entirely hardy under cultivation. The leaves are narrow and grass-like, and the flowers, opening in May, are borne on slender wiry stems, say, one foot high. In color they are a violet-purple, self-colored, except that the lip has markings of a deeper shade. The hood is curiously detached and distinct. It is not a very showy plant, but a useful addition to the hardy border.

Notes on Shrubs.

THE two or three species of *Styrax* in cultivation are well worth a place in all gardens of any extent, and it seems surprising that these pretty flowering shrubs are not more generally seen. They do not appear to be commonly known, and one rarely finds them outside of a botanic garden, a nursery or an enthusiast's collection. It may be that they have not won greater popularity because the flowers

do not endure very long or because they are largely hidden by the foliage. The habit of the shrubs is often rather open and straggly, but the foliage is clean and glossy, and, apparently, they are not liable to any serious disfigurement by insects or fungi.

There are two species of these shrubs to be had from nurseries, the Japanese (*Styrax Japonica*) and the American (*S. Americana*). Both are quite hardy in this climate if planted in good well-drained soil and not too much exposed, but if there is any difference in hardiness it seems to be in favor of the Japanese species. This is also the most showy and best worthy of cultivation. Its flowers, each composed of five large ovate petals, are something over an inch across, are of the purest white color, and are borne singly on slender stalks about three-fourths of an inch in length. They hang along the under side of the branches and produce a very beautiful effect, especially if the stems are tall enough to allow the blossoms to be seen from the under side of the somewhat horizontal branches. A serious detraction in the value of these flowers is that the whole corolla easily and soon becomes detached and falls in a single piece while yet looking pretty and fresh. The corollas carry the stamens with them, and after a heavy rain the ground is generally thickly strewn with the blossoms. The plant comes into good bloom here about the middle of June.

Less showy and handsome than the Japanese species is our native American one known as *S. Americana*, which is indigenous from Virginia southward. Its flowers are produced at the same time as those of the Japanese species, and apparently quite as abundantly. But they are much smaller, the petals being quite narrow, and they assume a strongly recurved position instead of remaining flat and horizontal like those of the Japanese species. They are also borne on shorter stalks, which renders them less graceful. The flowers of both have a sweet but delicate fragrance. Fruit is freely produced, and has something of the appearance of the dry little fruits of Linden-trees, being roundish and quite bony and with the calyx persisting at its base. The *Styraxes*, or *Storaxes*, as they are sometimes called, may be grown either from the seed, that grown here being quite good, or by layers or cuttings of the green wood. Layering is probably the easiest mode by which the amateur may obtain one or two new plants from one already established. As the seeds are dry and bony, they should either be sown as soon as ripe or they may be kept in a box with moist sand and subjected to the action of frost over winter and sown the following spring. Either of these *Styraxes* may grow and thrive if grafted on stocks of the Snowdrop or Silver-bell-tree (*Halesia tetraptera*), to which they are closely related botanically. The *Halesia* freely produces good seed here, and young plants for stock may be easily raised.

The recently introduced Japanese and Chinese *Viburnum dilatatum*, which was figured in the last volume of *GARDEN AND FOREST* (p. 150), has again flowered profusely, the blossoms being in most showy condition a day or two later than the middle of June. As a flowering shrub this might be called pretty, but it is hardly entitled to any more consideration for its inflorescence than our common Arrowwood (*V. dentatum*), whose flowers appear about the same time, or than the European Wayfaring-tree (*V. Lantana*), which blossoms somewhat earlier. The flowers are not very long persistent. *V. dilatatum* is to be valued most for its bright red or somewhat orange colored fruit in autumn, and for its late persisting yellowish autumn foliage.

Of the more showy *Viburnums*, those with large sterile flowers in addition to the perfect blossoms, we have no aboriginal kind which surpasses our own High-bush Cranberry (*V. Opulus*) in abundance and beauty of bloom in early June. More beautiful than this in its blossom is the Hobble-bush or American Wayfaring-tree (*V. lantanoides*), a rather common plant in nature, although it must be considered very rare in cultivation. This is much the earliest of all *Viburnums* to

blossom here, the first flowers on cultivated plants in the Arboretum opening as early as the 29th of April, while the sterile blossoms were conspicuous for some days earlier. The flat cymes of flowers of this species are broader than any other we know, and should a "snowball" form of this ever be produced it is likely to form an enormous cluster. Not the least interesting character of the Hobble-bush is the very large size of its thick, rough leaves, which always excite admiration, and which, when growing in the sunlight, soon take on a bronzy or purplish lustre. That a "snowball" form of this may be produced in the course of more general cultivation seems not unreasonable when it is considered that the three other species in general cultivation, and which bear showy sterile flowers in a natural state, have all given forms of the snowball character. These are our native Cranberry-bush, already alluded to, a native of Europe and Northern Asia as well as of our own coun-

as affect the common Snowball in almost every garden and cause the leaves to become wrinkled and twisted, not only to the disfigurement of the plant but to the detriment of its health, to such an extent as to interfere with the perfect development of its flowers. Applications of whale-oil soap will destroy these Aphides, but it has to be very thoroughly applied to be effective, because the distorted leaves offer secure hiding-places from all ordinary showerings or sprayings. When one of these shrubs is clean and well its flowers are carried with singular grace.

Arnold Arboretum.

J. G. Jack.

Indoor Work in July.

WORKING under glass is not an unalloyed pleasure during the midsummer season, but many of the finest stove-plants require attention if they attain their best estate even though the cultivator may find the temperature somewhat

Fig. 57.—Lumbering in Bear Meadows, Centre County, Pennsylvania.—See page 314.

try; the Japanese species, the double form of which has for some time been known in our gardens as *V. plicatum*, and the less common and less hardy Chinese species which bears the name of *V. macrocephalum*.

It is a curious fact that the wild-flowering type of *V. plicatum*, bearing cymes containing both showy, sterile and the small perfect flowers, has only been recognized in American and European gardens within a very recent time. It is known to botanists as *V. tomentosum*, and, like the High Cranberry-bush, its flowers are much more graceful and pretty than are those of the snowball forms. Nevertheless, the latter have come to be a necessity in all gardens. Of the two the Japanese Snowball is by far the best, because, not only are its blossoms handsomer and in finer clusters, but they endure twice as long in good condition as those of the common Snowball of our gardens. What seems to be a still greater advantage is that the clean dark green foliage of the plant seems to enjoy a singular immunity from attacks of Aphides and other insects, such

uncomfortable. This is the season of most active growth for many foliage plants, and there is, therefore, a certain amount of potting to be done all through the summer, in addition to the general overhauling that has been given in the spring; and while the growth of the plants is active, that of various insect pests is equally so; constant watchfulness is therefore needed since it is much easier to rid the stock frequently of a few insects at a time than to rid them of vermin after they have become badly infested. Some of the tender-leaved subjects, such as *Cyanophyllum magnificum* and *Sphærogyne latifolia*, are frequently attacked by mealy bugs, and in such cases very careful handling is needed, for the least bruise given to the young foliage when it is expanding will permanently disfigure it.

A camel's-hair brush is the most effective weapon to use on such plants for the removal of mealy bugs, and unless used very roughly it will seldom injure the young leaves. The plants above noted are among those requiring a rather high temperature and moist atmosphere to encourage their full development, but when this condition is attained, their beauty fully repays for the care given. Plenty of pot-room also should be given to these plants, and a light, rich compost,

and it should be remembered also that the soil should not be rammed very hard in the pots, and that the pots should be well drained.

Caladiums should now be in full growth, and if fine specimens are desired they should be potted on into large-sized pots or pans before the roots become stunted. A liberal quantity of dry cow-dung should be used in the potting soil, and, as soon as the pots become well filled with roots, an application of liquid-manure about three times a week will improve both the size and coloring of the foliage. And here may be an appropriate place to say that no collection of Caladiums is complete without *C. argyrites*, whose small, silvery-marked leaves are admirable either on a specimen plant or for cutting to use in table decorations.

One of the handsomest stove-plants of recent introduction is *Phrynium variegatum*, and though it grows best in a warm moist house, yet it seems to have enough endurance to stand very well for table decoration. It may be readily propagated at this season by means of cuttings formed from the young shoots or suckers taken off below the surface of the soil, which will soon form roots when placed in sand in a warm house. It is not too late to put in cuttings of *Azalea Indica*, though when the weather is very warm such cuttings require some care to guard against damping-off. The cuttings should not be taken from plants that are standing outdoors for the summer, for such growth is too hard to root readily.

The best wood for *Azalea*-cuttings is found in the form of soft young shoots from two to three inches in length, and taken off with a heel of the older growth attached, these being inserted in pots filled very firmly with light sandy soil, peat being preferable for this purpose. The pots should be plunged in a propagating-frame where they can be given some bottom-heat. The cuttings should not be exposed to strong sunshine, for if they are allowed to "flag" they seldom recover enough to make roots.

Many members of the *Gesneraceæ* help to make the greenhouse bright at this season, among which the *Gloxinias* are very prominent, and various *Gesneras*, *Tydias*, *Achimenes*, etc., vie with them in beauty and brilliancy of coloring. It should be remembered that all the plants of this family enjoy good living—that is, they should be well supplied with manure in the compost in which they are potted, and when the flowering period begins liquid-manure may be added quite freely.

Holmesburg, Pa.

W. H. Taplin.

Actinidia polygama.

WHEN visiting the Amherst Agricultural College recently, Professor Brooks pointed out two fine specimens of the true *Actinidia polygama* growing on his dwelling-house, which he brought home with him on his return from Japan after a twelve years' sojourn there. It appears that the species of *Actinidia* now in commerce, and called *A. polygama*, is *A. arguta*, a very different plant from the one here noted. *A. arguta* is a rampant grower, and when used on a dwelling-house soon shuts out all sunlight from the piazza, and then gets on the roof and displaces the eave-troughs in a way which renders continual cutting necessary to keep it within reasonable limit. When this plant was introduced into this country it was said that cats were very partial to *A. polygama* in Japan, but the American cat was found to be sublimely indifferent to *A. arguta*. The true species, however, Professor Brooks has found it necessary to protect about the base with wire guards, for, in his words, it out-Catnips Catnip as an attraction for these animals. This may be a peculiar way of verifying a species, but the evidence certainly seems admissible and to the point.

In appearance the plants have nothing in common. *A. arguta* is a vigorous grower, with heart-shaped foliage of a deep olive-green, and flowers that are polygamous, a feature which, perhaps, first caused the mistake in nomenclature. The plants of *A. polygama*, which Professor Brooks has, are not rampant, but vigorous enough for any decorative purpose where a twining plant is required, the principal beauty being in the foliage, which is for the most part of a beautiful pea-green, while about one-third of the foliage is suffused (not variegated) with an indescribable silvery lustre, often covering the whole leaf, but sometimes only a part of it, and beginning always at its base. When I first saw the plants with the sun shining on them and glistening in the light, I was compelled to ask if this was caused by the sunshine, but was soon shown that the color was permanent. Were the whole of the foliage silvered in this way the effect probably would not be half as beautiful.

The flowers of *A. polygama* are about the size and color of

an Orange-blossom, but with a sweet perfume peculiarly their own. It is much to be regretted that the nomenclature of Japanese plants gets so badly mixed up, as years will pass before the names of the *Actinidia* can be trusted as correct in catalogues. The plants of Professor Brooks are certainly of great ornamental value.

Among other things brought over by the Professor are a fine young specimen of the Japanese Lacquer-tree (*Rhus vernicifera*) and many beautiful varieties of Japanese Maples, especially the cut-leaved kinds. Some very dwarf forms of *Retinosporas* were here also—peculiar reminders of a peculiar country.

South Lancaster, Mass.

E. O. Orpet.

The Garden in June.

WHEN a garden has been stocked with a selection of plants to produce a succession of flowers, their blooming furnishes continual surprises. As the weeks advance, each with its varied flowers, it sometimes appears as if the flowers were spontaneous productions, so little care have the plants received. At the end of June the Larkspurs, Foxgloves, Hollyhocks, Lychnis, Coreopsis, Perennial Peas, Campanulas, Spiræas, Ascension and Golden-banded Lilies and Clematis are brightening all the borders with a wealth of bloom, together with the flamboyant Japanese Irises, and the dainty *Gypsophila* and *Galium*. The first of the annuals are in the flush of beauty. These are by no means ordinarily spontaneous flowers, except those like *Calliopsis*, Poppies and annual *Chrysanthemums*, which are usually self-sown. The charming Shirley Poppies, with their delicately formed and colored flowers, now cover the nakedness of the early bulb-bed.

Sweet Peas are now in full vigor. These plants have always bothered me, my soil being heavy and hard to work early in the year, when the seeds should be planted, besides which, as work is pressing at that time, they were often neglected. By planting seeds in thumb-pots in the cool house I have had much more satisfactory results. The pots were plunged in the earth slightly, and the roots penetrated the soil. In May they were carefully lifted when the tops were a foot high, the pots were broken off, and they were transplanted outside. Owing, perhaps, to their being planted at a suitable distance apart, they have grown away better than any plants I have raised outside, and are producing first-rate crops of flowers. Blanche Ferry (it is hard to get too many pink flowers) and pure white Peas cover my wants in these desirable plants. The perennial Peas (*L. latifolius*), white, pink and red, are ornamental low climbers with a profusion of flowers, valued by some for cutting. They are strong plants, needing care to keep within proper bounds. Mr. Orpet's note on *Lathyrus tuberosus* reminds me that there are a number of these strong plants which we sometimes feel like posting in the garden *Index Expurgatorius*, yet which, after all, should have only a note of warning attached. A plant ruthlessly destroyed in one garden may be highly valued in another. A list to be commended to those people who love flowers, but for whom they will not grow, might contain such things as these. It would be curious and interesting to see a garden filled with plants which are difficult to exterminate when once they had gained a foothold.

Hardy Carnations are now in full flower. It is interesting each year to sow with the annuals seeds of Carnations of a good strain. When small they can be transferred to the border, where they will prove reliably hardy the first winter. They bloom profusely, and will at least furnish a profusion of flowers for cutting, and sometimes there will be kinds to save. After the first season the stems become hard, and they are apt to be destroyed by winter frosts. The border Carnations, mostly English strains, are not safe plants to leave out in this latitude, especially when well grown, and it is well to pot them in the fall and keep them in a frame. Such kinds as the old Crimson Clove and its dwarf variety, Paul Engleheart, Souvenir de Malmaison, Mrs. Reynolds Hole, etc., are well worth the care required. Mrs. Reynolds Hole is an especially beautiful and distinct flower of an apricot shade. The popular Malmaison is perhaps better for the protection of glass at all times, as its massive flowers are rapidly rotted in wet seasons.

In the water-garden this is the time of the hardy *Nymphæas*, though nothing there makes such rapid advance as *Nelumbium speciosum*, whose wonderfully beautiful leaves expand almost visibly. Some *Callas* which had been kept growing, but rather dry in the greenhouse during the winter, were plunged in the tank in the spring, and prove rather interesting. The foliage is much shorter and sturdier than under glass, and the flowers have come freely, and prove very lasting. They

will be ornamental probably till the *Sagittarias* commence to flower with a change of effect. Of the pink *Nymphæas* there is now a nearly complete series through the entire gamut of color between the slightly tinted *N. carnea* to the deep carmine-rose of *N. odorata exquisita*. This last has a color tone in the way of *N. rubrum*, but lighter. Of the various white *Nymphæas*, among which there is a wide difference in form, I am inclined to give the palm for beauty to *N. Marliacæ albida*. This is a flower of the largest size, with petals somewhat narrower than those of *N. alba*. The color is a lustrous silvery white, very distinct and beautiful.

Elizabeth, N. J.

J. N. Gerard.

The Importance of Microbes in the Cultivation of Plants.

MONSIEUR CHARLES NAUDIN, in an article in the *Revue des Sciences Naturelles*, gives a plausible explanation of the frequent failures which occur in growing exotic plants. Even though the conditions surrounding the plant may apparently be favorable to its development, it often seems that an essential element is wanting. Monsieur Naudin considers this element to be, in a great many cases, the fertilizing microbe which is found in the soil in which the cultivated species originally grew.

Several facts support this theory. He cites cases relating to certain species, in which it has been impossible to grow the plants, whatever the composition of the soil in which they are placed. His own experiments, which were carried on with seedlings, strongly incline him to the belief that the presence of certain micro-organisms in the soil is an indispensable factor for the development of many plants. It is well known that fertile soils swarm with several kinds of microbes, and it also seems that certain plants are infested with microbes peculiar to them. Monsieur Naudin says that these may be transmitted from one generation to the next, and even though the plant may not die outright, its growth may be checked and its life shortened, if certain lower forms of life are not present.

Correspondence.

New England Country Houses.

To the Editor of GARDEN AND FOREST:

Sir,—Your correspondent, S. P. S., who does me the honor to agree with me in a taste for warm colors in house-painting, suggests that stone and brick would in the end be more profitable, as well as picturesque, building materials than wood, which requires frequent painting and occasional renewing. While agreeing with the writer wholly as to the more interesting and picturesque character of solid construction, I still think that there are serious objections to using brick and stone for houses in a New England village.

These materials, so pleasantly cool in a continuously hot summer climate, are apt to make a dwelling damp and cold when our variable wind whisks round suddenly to the north-east after days of tropical heat. So long as the weather is cool enough to permit a light furnace fire, stone houses are very agreeable, but the torrid temperature of our summer days never fairly warms through a thick wall, and the change from out-of-doors is often chilling and uncomfortable on a day when a wooden house would prove just pleasantly cool. To be sure, a fire on the hearth can be easily lighted, but it requires an army of servants to attend to open fires in many rooms, and the consequence is that one often goes unwarmed rather than take the trouble to attend to the falling logs, which it is unsafe to leave, and the consequent chill received is unwholesome. There is an undeniable dampness about brick and stone dwellings here, which shows itself in the rust on steel and iron objects, in mold on neglected shoes, in spots on the walls of shut-up rooms, which proves that they are seldom thoroughly dry without artificial heat. Even in the brick-ended houses, with wooden fronts and backs, common in some old-fashioned towns, there is the same trouble from the collection of mold and rust even in houses not shaded by trees. This is not experienced in wooden houses unless in very wet and shaded localities, which shows that there is a freer circulation of air in frame-dwellings, and a healthful dryness even in shut-up portions during the summer.

Sea-side buildings of stone are apt to leak around the windows during a driving storm, so that much damage is often done even in an apparently well-built house, and in cold winters the pointing with mortar is apt to crack and let in the rain.

Severe seasons are also apt to throw rubble-work wholly out of place, and to occasion a great deal of damage in houses built of it. Moreover, is rubble-work in itself proper material even for the lower story of a house? To me it always seems to wear an air of insecurity, as if it might fall to pieces at any moment, especially when invisibly pointed, as is now the fashion, so that there is apparently nothing to hold the round stones together.

When we see what freaks the lifting of frost will play with unmortared walls of the most massive construction, throwing them down till huge gaps are visible in them, one may well hesitate to employ anything that looks as if it might be liable to that sort of upsetting when the mercury goes below zero. Of course, the walls can be constructed to stand firmly, but anything which looks insecure is architecturally faulty, however picturesque it may be. Frost and rain certainly do queer things in the Yankee climate, which shows a special animosity to outdoor plaster of all kinds, and when a high wind blows, almost any one feels more comfortable in something that may possibly blow away all in one piece, but will certainly not tumble into fragments like a house of cards.

But, after all, the very serious objection to brick and stone is in the immense difference in the first expense of building with these materials, especially outside of a town where workmen are easily to be obtained; for in the country only a few men understand the business, one or two bricklayers usually sufficing to a village, and as many stonemasons having charge of the construction of cellars. In any case an outside stone wall costs at least twice as much as wood. As to painting, a brick house has to be oiled or painted about as often as a wooden one, to keep the water from driving through its porous structure, and the additional pointing which must be renewed occasionally in white-lead, also painted, is another item of expense. Also, stone and brick buildings have to be constructed on a much larger scale than wooden ones, to admit of an air space between the outer wall and the lathing to prevent dampness constantly penetrating the interior. Another point is the transportation of the heavy materials, which is very expensive compared to the transportation of wood, even if the stones are close at hand, as any one who undertakes to lay a few score feet of mortared wall of stone on his own land soon learns to his concern.

All these objections have weight with those to whom expense is an object, and there are few people who live all the year round in the country who do not have to count the cost of their houses with considerable care. The melancholy result of such calculation reveals that the picturesque is invariably the most expensive as well as the least durable of ways to build. Numerous gables represent places for leakage; stone and brick laid in mortar require close attention in our bitter climate, and the angles and recesses, so charming in a wooden house, render it the more difficult to keep in order. In short, true economy in building, both for durability and cheapness of maintaining and heating, was obtained by our colonial ancestors with their square uncompromising domiciles; and to this day these frame-dwellings, with such modification of their bareness of outline as may be obtained by verandas and bay-windows and skillfully placed railings, still remain the most profitable houses to build, and the least expensive to keep in order in New England, where the accessible stone is almost always very difficult to cut and handle, unlike a lime-stone or gneiss, which latter flakes off in a way that makes it ready for use without undue labor.

M. C. Robbins.

A Foreigner's Impressions of America.—III.

To the Editor of GARDEN AND FOREST:

Sir,—My first impressions of America had left me with a vague sense of perplexity at the inconsistency between the glorious woods and the neglected front yards—my spring impressions only served to deepen this feeling. I did not feel it so much at first. It was so delightful to be out of town again, and the charm of Bean-stalk Land, of a new country, more open and free and bright than our ordinary European suburbs, was upon me strongly. The Boston suburb I had chosen is a very lovely one, rural and dignified. The older houses retain their original extensive grounds, and in the newer streets near the station the houses have not yet begun to crowd each other. There were but few fences, but that only seemed in keeping with the hospitable, old-world character of the large places, while the smaller grounds afforded full views of sparkling young grass and Peach-trees in bloom, entirely in harmony with the strange beauty of the keen spring air.

As April deepened into May, however, with the first glory

of the young grass, the ethereal beauty of the Peach-blossoms and Pear-trees departed and was succeeded by an exuberance of teeming life in the woods and fields that seemed to call for a corresponding joyfulness in the gardens. As my walks extended to long tramps and drives about the country and visits of curiosity to other suburbs of Boston, I sadly missed the English gardens. Had I never gone into the woods I might have thought that this beautiful land, with its abundant sunshine, was one where flowers did not thrive. But the woods had quite a different tale to tell. The variety of trees and blossoming shrubs and decorative flowers—many of them looking to me as if they had strayed from some garden—filled me with ever-increasing wonder and delight; and yet I knew that the woods which were accessible to me did not give me any adequate notion of the resources of New England woodlands. The few really charming gardens I saw only served to increase my perplexity by showing me what might be done in this favored climate, which seems to command the resources of both the North and the South. I remember one garden in particular, a bower of delight, with magnolias and fruit-trees, standing about in beds of strawberries, and holding up their crowns of blossom against a distant background of picturesque White Pine, while clusters of English Primroses nestled under the arch of a vine-covered trellis, suggestive of Italy. The Wistaria grew as luxuriant as it ever does on the shores of the lake of Como. The herbaceous borders were broad bands of solid color and splendid growth, and all this was planted on a slope that helped to give beauty to the perspectives, and was surrounded by a sturdy fence that made the charm complete. This garden and a few others like it were the luxuries of wealthy amateurs, it is true, but I do not see why the same thing could not be worked out on a smaller scale by less-favored mortals in suburban homes.

At present the ideal seems to be grass and a few shrubs or trees. A few words first as to this ideal. Such as it is, it might be much more artistically treated than is now generally the case. Even admitting that medium-sized suburban homes are generally deserted during the summer, and that for them it is well to have lawns, terraced or not, planted with some shrubs and trees that require no special care in summer, and possibly with a bed or two of spring flowers, it does not follow that these shrubs and trees might not be selected with taste and care. It ought to follow that people should put at least as much care into the choosing and arranging, once for all, of their shrubs and trees as into the choosing and disposing of their furniture. One belongs to the house as much as the other. An expensive house on a poor plot of land looks no better than a bunch of choice grapes on a coarse platter. Pretty surroundings, that give one something delightful to look out upon at all seasons of the year, are as important for the drawing-room as the furniture, and, indeed, if the question of cost should be urged, I should say that a choice shrub or two more in the garden, and a fashionable knick-knack the less in the parlor, would decidedly improve the parlor.

It has not seemed to me that many of the dwellers in suburban homes held this view of the matter. I have not observed that the women who go to art-schools, museums and lectures with great assiduity, for the purpose of educating their taste, have taken any pains to put the art-knowledge they have acquired to profitable use in their gardens. Looking over Japanese prints would teach them, if their own observation had not done so, that a Peach-tree in bloom would look all the better for having a background of White Pine, or that one or two detached plants of Iris, showing the beautiful growth of the flower, look better than a whole square patch of them, while everything else that they really saw and understood would be teaching them minor details about grouping and detaching, about line and color, which might all be applied in their own gardens. There is no working palette more varied and delicate than that offered to the garden artist by spring in New England, with the tender pinks, pure whites and golden yellows of the flowering shrubs and trees, the splendid dark foil of the White Pines, all the golden and bronze greens of the young leaves, and the gorgeous, distinct note of the Red Maple. A woman with whom artistic tastes had become second nature, and were no longer a mere fad, might, if she cared, convert even her little fenceless plot of grass and shrubs into a thing of beauty during the seasons of the year—spring and autumn—that the family spend in their suburban home.

A woman of artistic tastes would not long be satisfied with mere grass and shrubs, especially if her grass was terraced. A bare, terraced, grass-laid yard around a handsome house is a double anomaly. Not only does a fine house call for fine grounds, but any arrangement in terraces calls for a formal garden. Many of these terraced yards have a strip of peren-

nials along one of the walks, it is true, but one bed on one side is not enough to carry out the idea of symmetry, irresistibly suggested by the terraces and the straight gravel walk leading from the sidewalk up to the house. The least one can do is to accentuate this walk and the small terraces themselves by shrubs or plants in pairs, either planted in pots or direct in the ground, as the case may be, and large or small, costly or simple, according to the taste and means of the individual. For wealthy suburban homes, where the people can afford to make an arrangement with a florist, I can think of no more beautiful June decoration than an avenue of the shrub Wistaria, with its indefinable air of distinction. Indeed, in this favored clime, there does not seem to be any kind of spring or early summer plant, shrub or tree, that lends enchantment to other lands, which is not available for purposes of gardening here, while the native woodlands themselves are rich in varied and beautiful growing things. But the passion for gardening, which would run riot in all this abundance, does not seem to exist, at least among the residents in the suburbs I have seen. Why is this? I wonder. Do not Americans love and appreciate their own beautiful woodlands? How can they see them without loving them, and how can they love them without trying to transplant some of all this woodland wealth to their private grounds and add a new charm to their home-surroundings?

Milton, Mass.

The Forms of Trees.—I.

The following extracts from a paper by Gustav Eisen, read before the California Academy of Science on the 15th of last February, and reprinted in part in the April issue of *Zoe*, are interesting to all students of trees:

"A traveler," he tells us, "from the arctics, or from the high wooded mountains in any district of the world, cannot but be impressed by the different forms which trees and shrubs assume in the respective regions. Nowhere is this difference in form more striking than between the trees inhabiting the Pine region of the Sierra Nevada and those which grow on the lower plains in the interior valleys." . . .

"In the high Sierras, for instance, in that region below the snow-line, where the Pines and Spruces dominate, we find that almost every shrub and every tree resembles the other in a general way. The trees are tall and erect, with a central undivided trunk, from which the branches slope down toward the ground. The shrubs, again, are low and depressed, spreading out horizontally, forming dish-like masses, hugging the ground instead of seeking the sky. A few thousand feet further down in the region where the evergreen Pines and Spruces have ceased, the trees as well as the shrubs begin to assume a different aspect. The trees in this region are not so erect, their branches are less sloping, their crowns extend further, the trunks are often branching; there is, in fact, a decided difference in their general form. The shrubs, again, are more erect and bushy, forming often dense masses, which show little or no tendency to flatten out.

"If we again follow the vegetation further down to the plains the change in form is yet more pronounced. The trees are here, as a rule, branched close to the ground, their crowns are wider and spreading, the branches drooping and often sweeping the ground. The general form, which in the higher Sierras was that of an elongated pyramid, has here changed and become globular. We may call these, respectively, the Spruce form and the Oak form. In the higher mountains we rarely meet with the Oak form, at least not in evergreen trees, and on the plains the Spruce form is equally rare. There are some exceptions to this rule, but they are few, and in no way interfere with the theory which I will here set forth and endeavor to prove. Before we dwell upon the causes which have been and yet are operating in creating and maintaining these characteristic forms of trees, it is necessary to first consider those causes which combine in effecting a change in the form of trees generally.

"Nearly every visitor to the wind-beaten and open sea-shore has noticed the characteristic forms of trees and shrubs growing there. The shrubs spread close to the ground, the trees lean toward the interior, their crowns spread out horizontally, and their branches are thorny and knotty and continually bent. Such a sight is common everywhere in exposed places. In sheltered localities inland these same varieties grow upright, their crowns become less horizontal, the branches less twisted, and the same shrubs, which on the sea-shore hug the soil, grow here straight and send out slender branches. Even to the least observant the force that operates here and causes the

trees and shrubs to so change their shapes is the wind. When we see such trees and shrubs painted on a canvas we know at once that the landscape is a wind-beaten one, and that the vegetation is struggling against a force which is trying to destroy its foothold.

"But while the wind is especially active on the sea-shore in changing the natural, or perhaps the original form of the trees and shrubs, it is similarly effective to a lesser degree in any locality at all exposed to winds. The interior plains, the cliffs on the sides of the desert, the high mountain-peaks, the elevated plateaus, the table-mountains, the slopes of the more sheltered sides of islands—in fact, everywhere—may the power of the wind be perceived.

"The effects of the wind may be temporary or permanent; temporary, if the plant retains its original form and outward appearance when removed from the windy region to a sheltered one. This is by far the most common effect, and especially refers to shrubs. Many instances may be cited, but I will only mention one. *Baccharis pilularis*, which grows everywhere on the coast around San Francisco, clings typically to the soil and sand-hills where exposed to the wind, while on the north side of Tamalpais, where the shelter is perfect, and even in the Oak-scrub of Golden Gate Park, it assumes an erect form. So different is the outward appearance between these two forms that the former has been described as a distinct species, *B. consanguinea*.

"Similarly on nearly all our high mountain-tops we meet with Scrub Pines growing in the crevices and clinging to the rocks like real coverlets of verdure. But the same species may be found farther down in the elevated valleys growing erect with sloping branches and undivided trunks. Such instances are common. I may, however, here especially recall the dwarf and scrubby *Pinus monticola*, growing in the cañons on the slope of Mount Dana, while farther down splendid specimens are crowding the sheltered meadows.

"As an instance, again, where the effects of the wind have been partly permanent we may point to the Monterey Pine (*P. insignis*) and to the Monterey Cypress (*Cupressus macrocarpa*). Mature specimens of these varieties assume always horizontal crowns, even when growing inland, and only during their earlier growth do they show a tendency to grow erect like most species of Pines or coniferous trees generally. We may presume that if the evolution of a species is accompanied by this continued wind force the latter will, to a great degree, mould the outward form of the species. If, again, the evolution of a species takes place under various conditions of wind and calm the form of the species will be variable, according to exposure.

"The effect of the wind, while apparent everywhere, and while found in every climate and in every country, is, however, not the most powerful agent in shaping the forms of trees and shrubs. The snow which part of the year covers vast territories, often to a depth of thirty or more feet, has a great influence upon the forms of all plants which are exposed to it for a longer or shorter time.

"As the effects of the snow depend chiefly upon the resistance to pressure, it will be seen that evergreen and deciduous trees must be unequally affected. The foliage of the evergreens offers much more resistance to the snow than do the bare limbs of trees and shrubs which during the winter season are void of leaves. In some horticultural districts, where snow but seldom falls, and where, accordingly, such trees as Olives, Oranges and Lemons are cultivated successfully, an occasional fall of snow may do, and has in many instances done, considerable harm. We know that when the snow lodges on the evergreen and upright limbs of Orange-trees, these limbs become so heavy that they break down, more or less ruining the trees." . . . "Those limbs which point upward do not yield readily under the pressure of the snow, and trunks which are repeatedly forked will, if the pressure is heavy enough, split lengthwise. In case the trees in question had possessed downward sloping limbs and an upright, undivided or standard trunk, the effect of the snow pressure would have been less dangerous; the limbs would have yielded to their snow burden, which, when melting, would have slipped off, leaving the limbs free, and the undivided trunks would not have split, and the trees would have escaped without injury. If such snowfalls were frequent and regular, only such varieties could be cultivated as were possessed of downward sloping limbs and upright trunks. All trees shaped otherwise would gradually be ruined and their cultivation become impossible. These last remarks refer only, or at least principally, to evergreen trees. If the Orange-trees, which we gave as an example, instead of being evergreens were deciduous—that is, presenting only bare limbs in the winter, like Peaches, Apricots and Pears—the pressure of the snow would not have injured them, at

least not by breaking their limbs and splitting their trunks, and their cultivation would not necessarily have been abandoned. If we consider a forest instead of a horticultural district, we will find that the conditions are there very much the same. The yearly snowfall, if only heavy enough, tends to break down and destroy all wild evergreen trees which do not possess a form suitable to resist the heavy snow mantle. Trees which would thus suffer would be all evergreen trees, with spreading crowns, such as Live Oaks, Laurels, Madroña, certain Pines, such as Monterey Pine, Digger Pine (*Pinus Sabini-ana*), Italian Pine (*P. Pinaster*), Lebanon Cedar, and the hundreds, if not thousands, of other evergreen trees which inhabit regions below the regular snow-line.

"Nature thus eliminates from snow-visited forests all evergreen trees which are not suited to resist the pressure of the snow. On the contrary, the snowfall makes it possible for all those trees to live and survive which, through their outward form, are able to easily shed the accumulated snow. As regards deciduous trees, no such upright trunks and sloping branches are necessary, as the bare limbs do not accumulate the snow or suffer under pressure. If the above is true, the forests of snow-visited districts will be found to consist of only such varieties of trees as possess the requisite form—that is, evergreen trees with upright, undivided trunks and downward sloping branches, as well as of deciduous trees of various not especially characteristic forms. Upon examination this will also be found to be the case.

"A visit to the high Pine-forests of Sierra Nevada shows us just such forests. Nowhere is the snowfall heavier and nowhere is the characteristic form of the evergreen trees more pronounced. This is also the case in all other snow-visited regions where forests are at all able to exist. Where the snowfall is the heaviest and lasts the longest all evergreen trees, at least during a certain period of their life, possess the required pyramidal form. Evergreen trees of any other form would in their struggle for existence have little or no chance to compete with better-equipped neighbors. It follows, also, that the less the snowfall the less characteristic will prove the pyramidal form in all evergreen species, while lower down the mountains on the warmer slopes the pyramidal form may be expected to be entirely absent.

"To refer to our nearest high mountains, the Sierra Nevada, we find thus on the snow-belt such trees as *Pseudotsuga taxifolia*, *Abies amabilis*, *Pinus Lambertiana*, *Libocedrus decurrens*, *Sequoia gigantea*, etc. All these show in a characteristic way the pyramidal form, the snow-shedding branches and the undivided trunk. We find in this region no large Live Oaks, nor any large evergreen trees of globular or goblet shape. But in the region immediately below the heavy snow-belt the characteristic pyramidal shape is entirely absent. The forms of the evergreen trees are here evidently regulated by other agencies. In this region we meet with several evergreen Oaks with large crowns, spreading branches and repeatedly divided trunks. The Pines also, like *P. Sabiniana*, are characterized by their forked trunks, their upright limbs, and by their general resemblance to deciduous trees. As regards shrubs of all kinds, they are hardly less influenced by snowfall. In the snow-visited forests, at least, the evergreen shrubs show a low depressed form, sometimes spreading out like dishes on the ground. Other species, again, like the Manzanitas, possess repeatedly zigzag bent limbs especially adapted to resist the pressure of snow and wind. Such zigzag form is also possessed by the branches of trees, greatly assisting them to resist outside pressure of any kind. Thus, while the lower or central branches of most of the Pines in the snow region slope downward, the upper limbs, which are naturally less exposed to snow pressure, assume a horizontal position, but are compensated by being repeatedly bent and furnished with heavy knees. Such limbs are generally seen in the various species of Pines, such as *P. Lambertiana*, *P. contorta*, *P. Jeffreyi*; also in *Sequoia gigantea*, etc., while they are almost absent in the Spruces and Firs, the sloping elastic limbs of which continue to the tops."

Notes.

The Clarke Memorial Medal was recently bestowed by the Royal Society of New South Wales upon Mr. Thistleton Dyer, director of the Kew Gardens, in recognition especially of the valuable services which he has rendered to the agricultural and horticultural interests of India and the Colonies.

The Japanese *Ligustrum Ibo* is still too rarely seen in our gardens. It is one of the very hardiest and most desirable of the shrubs of its class, and just now it is covered with its short drooping racemes of pure white flowers which are so fragrant

that they perfume the air in all the neighborhood of the plants. Its free growth and graceful habit, in which it excels other Privets, make it beautiful, too, after the flowers have disappeared.

At a recent meeting of the Société Nationale d'Horticulture de France, Monsieur Cornu exhibited the yellow-flowered Pæony, raised from seed collected in Yunnan by Delavay, to which Monsieur Franchet has given the name *Pæonia lutea*. It is a small-flowered species of no ornamental value, but interesting from the unique color of the flowers and the possible influence it may exert in the creation of a new race of yellow-flowered garden Pæonies.

Mr. C. L. Mann, of Milwaukee, writes that an Elm-tree cut last winter at Sutton's Bay, Leelanaw County, Michigan, scaled 6.487 feet, board measure, by Doyle rule. The first eight feet of the trunk were cut off, and not taken out on account of shake, and a piece of the trunk further up had attached to it a burl about six feet in diameter, and six feet of the trunk were wasted to avoid the task of handling this. A deduction was made for defects in the first log.

The hybrid *Lælia* which was raised by Messrs. Sander & Co., of St. Albans, England, from *Lælia purpurata*, fertilized with the pollen of *Cattleya Mossiæ*, and named *Arnoldiana*, is now blooming in the collection of Mr. Hicks Arnold, of this city. The plant justifies all that was said in its praise when it was awarded a medal and a first-class certificate rather more than a year ago at a meeting of the Royal Horticultural Society, in London. Mr. Arnold's plant carries eleven flowers, and they show the good qualities of both parents, especially in the richness of their coloring, from the pale purple of the petals and sepals to the brilliant dark crimson of the lip.

Syringa Japonica, the great tree Lilac of northern Japan, certainly improves with age, and the large plants in the gardens of eastern Massachusetts, where this fine plant was introduced several years ago through the agency of the Arnold Arboretum, are better than ever this season, being covered with their immense clusters of creamy white flowers, which stand up boldly above the masses of rich dark green foliage. Among small late-flowering trees *Syringa Japonica* here at the north has no equal when once it is established in deep rich soil with sufficient room to insure the growth and ripening of its upright rather rigid branches which, when the plants are well grown, form a compact rather formal head. The largest plants in Massachusetts are now nearly twenty feet high and twelve or fifteen feet through the branches.

English fruit-growers are now compelled to compete with the most distant countries, for rapid transportation is making proximity to market a secondary factor in fruit-culture. A few years ago apples were first shipped from Australia to London, and this fruit was so much superior to that grown in England that the latter was, in some cases, practically driven from the market. This year Mandarin oranges have been sent to England from the province of Nagpur, in British India, and the fruit is of such excellent quality that it rivals the oranges grown in less distant countries. Peaches grown at the Cape of Good Hope have also been successfully shipped to London. They were sold in London early in February, the demand being strong. The first crate, containing 35 peaches, sold for 80 shillings. Such prices will be a strong inducement for further shipments.

The *Gardeners' Chronicle* has an interesting note about a Tulip-show which for sixty-seven years has been held at the Orange-tree Inn, Butley, a small village near Macclesfield, England. So popular is it with the Tulip fraternity that many admirers of the flower are attracted to it from Manchester, Macclesfield, Stockport, etc. The show is conducted according to all the old traditions: the flowers are staged in ginger-beer bottles in one room; in another sit the secretary and the exhibitors, and as the flowers are judged, stewards bring to the secretary the blooms awarded prizes; the names of the varieties and the exhibitors are entered by him in a book, and the proper cards affixed to them; they are then returned to the show-room and arranged on a sloping stage—like an old-fashioned plant-stage—placed at one end of the room, where they are on view for a few days, non-subscribers being "admitted on payment of silver at the doors." If any one would witness something of the old enthusiasm which stirs the Tulip-growing fraternity, they should pay a visit to the Butley Tulip-show. One curious proviso in the schedule of prizes is, that growers may be required to prove on oath the flowers they bring to the show were grown and bloomed by them.

At a recent meeting of the Torrey Botanical Club in this city one of the members described an interesting collection of New York plants, accompanied by many drawings, which he had been shown at the British Museum. The collection is in book-form and is prefixed by the following statement, written in New York in 1782 by F. von Langenheim, a captain in the Hessian army-corps: "This manuscript, which has never been printed, contains part of the Flora of New York, and was composed by a lady, the daughter of the Governor, Cadwallader Colden, well known for his botanical works, and a physician as well. This lady married a doctor of medicine, Farquhar, a Scotchman by birth, and she died soon afterwards. Some of the names are according to her father and according to Gronovius, and some are according to the Brandenburg Dr. Schœpff, who has read this work. The trivial names are according to Linnæus. This work is a remarkable one, because it is that of a lady who possessed such a love for botany that she learned Latin, and, judging by its nature, is so worthy and correct that it contains many, even minute, things." Governor Colden, the lady's father, was the author of *Plantæ Colden-shamiæ in Provincia Novæboracensi Americæ sponte crescentes quas ad Methodum Cl. Linnæi sexualem Anno 1742, etc.*, which in 1749-1753 was published in the *Proceedings of the Royal Society of Sciences*, at Upsala, as the earliest special contribution to the Flora of New York State.

Under the title of *Dictionnaire Pratique d'Horticulture et de Jardinage*, Monsieur S. Mottet has commenced the publication of a translation of Nicholson's *Dictionary of Gardening*. The value of the original work will be increased in its new form by various changes and additions which the translator promises with a view of adapting its contents to the climate of France and the methods of French horticulturists; and that special parts of the work may be treated in the most authoritative manner possible, and that cultures, especially French, may be properly treated, he has secured the co-operation of such distinguished experts as André, the Vilmorins, Bellair, Legros, Alluard, Dard and Mottet, whose contributions will be signed by the initials of the authors. The work will be completed in eighty parts, each of forty-eight pages, accompanied by a chromo-lithograph, a part being promised each month until the completion of the work—that is, at the end of six years. The price of each part is thirty cents, and subscriptions can be sent to the Libraire Agricole de la Maison Rustique, 26 Rue Jacob, Paris, or to Vilmorin-Andrieux et Cie., 4 Quai de la Mégisserie. The colored plates in the two parts which have already reached us are devoted to a group of Acacias showing flowering branches of four species, and to a group of *Anemone fulgens* and its varieties. The cuts, which give so much value to the original work, are reproduced in the French edition. Judged by the parts already before us, Monsieur Mottet's publication promises to be a substantial and valuable addition to garden literature.

Recent issues of German horticultural journals report wide and active interest in the proposed displays at the Chicago World's Fair. Meetings called in various places to awaken such interest and make practical arrangements for contributing have been largely attended; and at one held in Berlin, where not only local horticulturists but also those from distant towns were present, almost every person announced his intention of exhibiting. At this meeting the government grant of 10,000 marks for the assistance of exhibitors was voted far too small to cover needful expenses, as these would involve, for example, the immediate dispatch of an agent to remain in Chicago until the close of the exhibition; and it was therefore decided that all expenses in excess of this grant should be shared between the exhibitors. Since last January a committee has been actively at work in Hamburg; the contributions from this place will be particularly numerous; and a special trade-exhibition has been arranged for the month of September. At one time, German exhibitors were discouraged by a report that certain American firms had threatened by letter to withdraw their patronage from German firms should these exhibit at Chicago. But Mr. Mason, our consul at Frankfort, has now made public a telegram received from the director of the horticultural section in Chicago, which declares that there is "no truth in the rumor of a boycott," and has promised to investigate the sources of the rumor, and to recommend that, if such threats have indeed been made, those who made them shall themselves be excluded from the exhibition. Such a punishment would be none too great for conduct of so selfish, short-sighted and disloyal a sort; but we cannot believe that any American horticulturist has indeed been guilty of this conduct.

A Suggestion.

A CORRESPONDENT, in describing in another column the beauties of Roan Mountain, in North Carolina and Tennessee, refers to the destruction of the forest in the valley of the Doe River, in the latter state. More than once in these columns we have alluded to the wealth and beauty of the southern mountain-forest, which no other forest of deciduous trees equals in variety, attractiveness and splendor. It is as wonderful in its way as the Sequoia and the Redwood-forests in California are in their way, and far more beautiful and interesting. On the slopes of the high mountains of Carolina and Tennessee the principal trees of the Appalachian forests attain their greatest size and perfection, and in a ride of a few hours, covering a rise in elevation of 4,000 or 5,000 feet, one may see growing in their supreme perfection the trees of the south, like the Magnolias, the trees of the middle states, like the Ashes, the Oaks, the Maples and the Lindens, then the Birches, the Pines, the Mountain Ashes and the Spruces of the extreme north. In these forests the Chestnut grows to its greatest size. The Wild Cherry produces trunks six feet in diameter, and the Tulip-trees send up stems still more massive. The White Oak, the Red Oak, the Black Oak, the Chestnut Oak and the Scarlet Oak attain here their greatest height and girth of stem; here the Snowdrop-tree, or Halesia, the shrubby ornament of our northern gardens, develops a great trunk free of branches for a hundred feet above the ground; here are the greatest Ash-trees on the continent, the noblest Hickories and the tallest and state-liest Hemlocks. In this wonderful region the Kalmia grows to the dimensions of a good-sized Apple-tree, the Tupelo is a forest-giant and the Rhododendrons are tree-like in size and habit. The Sweet Birch of the Smokies dwarfs the biggest Birch-trees of the north, and the Sugar Maples of New England are as pigmies in comparison with the Maple-

trees of the south. In early spring the floor of the forest is lighted up by the fiery heads of Azalea calendulacea, which decks for miles the upper mountain-slopes with solid masses of bloom, while Azalea arborescens dips its pure white fragrant flowers into every mountain-brook.

What has happened to the forests of the Doe River valley will happen to the forests of every other valley of the Appalachian Mountains, which sooner or later must give up their stores of timber to supply the wants of a nation which for more than a century has been wasting its fairest heritage. The best Walnut-trees and the best Cherry-trees in all the mountain-region have been bought up singly by speculators and converted into lumber. It is now almost impossible to find a large individual of either. Many of the remotest and most inaccessible valleys of the Smoky Mountains have already lost their best Tulip-trees, and as the demand for timber increases the wood-chopper will penetrate deeper and deeper into the recesses of these mountain-forests.

The destruction of all the large trees is now only a matter of comparatively a few years, and unless some measure can be adopted for the preservation of a block of this forest the inhabitants of America born fifty years from now will go to their graves without the opportunity of seeing the character of the trees their country produced when all conditions favored forest-growth.

The nation has decided to hold forever, for the instruction and enjoyment of the people, a portion of the Sequoia-forest in California; the civilized world has applauded this action. Not less important is the preservation, for all time, of a portion of the southern deciduous forest. This can only be accomplished by the nation, as any adequate forest-reservation in the southern Alleghanies would extend beyond the borders of a single state, and there is certainly nothing within the power of Congress to accomplish that would afford a more useful object-lesson or indicate a higher degree of civilization than the purchase and protection of a good example of this forest, that future generations of men may see and understand the capacity of American soil, and the beauty and majesty of its supreme products. It would not be difficult to select an area of moderate extent which should serve this purpose, and the first cost and subsequent care of such a reservation would not be large in proportion to the material benefits to be derived from it. Roan Mountain itself, on many accounts, would make the best reservation; the summit is exceptionally beautiful, and may be used by the public without injury to the forest; the peculiar position of the mountain makes the view from it more varied and extended than that from any other peak of eastern North America, while the railroad brings this mountain almost to the doors of a large population. These advantages, and the fact that the summit of the Roan is already occupied by a large and prosperous hotel, which is soon to be extended, would greatly add to the cost of the property, while the value of the mountain, as a forest-reservation, intended to illustrate the character and quality of the southern forest, is lessened by the removal of large trees of several varieties. A cheaper reservation, and one that would be more desirable, so far as relates to the actual condition of the forest, could be found in the Big Smoky Mountains, or in one of the cross-ranges which connect them with the Blue Ridge. Here a forest almost primeval and of unapproachable grandeur can be found, although a reservation made here would for many years at least be difficult of access, and would lack the extended view and open Rhododendron-crowned summit of the Roan.

The subject is one of importance to all Americans interested in the prosperity and future of the country, and Congress cannot do better than appoint a commission of experts to investigate the matter of a forest-reservation in the southern Alleghanies, and, if such a reservation is found practicable, to devise means for securing and maintaining it. If such a reservation can be made, and a few square miles of the Redwood-forests of the California coast can

be reserved, examples of the three most interesting forests in the world, the southern-Alleghany deciduous forest, the coniferous forest of the western slope of the Sierra Nevada, with its Sequoias and Sugar Pines, and the Redwood-forest of the Pacific coast, will be saved to interest and instruct future generations of men who will see in them the great marvels of vegetable growth which, without the intervention of the nation, are doomed to speedy destruction.

The Terrace at Haddon Hall.

WE print the accompanying illustration of the terrace at Haddon Hall (p. 329) as one of the most beautiful examples which could possibly be found of a combination of architectural and natural forms. The battlemented Elizabethan wing of the famous house is fine in itself, owing to good proportions and a noble simplicity of design; and the terrace with its broad flight of steps is well in keeping with it. But if we fancy them deprived of this foreground of level turf, this mantle of Ivy, and this background of luxuriant trees, we imagine a commonplace although good, instead of an extremely dignified, beautiful and individual effect. Nor, in the aspect of the verdurous environment, could we fancy any change which would be an improvement. The solid clipped hedge between the path and the walls gives the latter a base which brings them into harmony with the lawn. The Ivy grows in characteristically heavy masses but has not been allowed to infringe unduly upon the windows, and the contrast between the draped and the naked battlements is very picturesque. Then, just at the end of the house, the peculiarly heavy way in which the Ivy falls from the top of the wall admirably unites it with the trees beyond. These trees, rising back of the terrace, give it great dignity and make it seem a part of the main structure rather than an addition to it; and the Ivy does not clothe the terrace wall so thickly as to conceal its character. Of course in such a case it is impossible to say how much of the perfection of the result has been due to artistic gardening skill, and how much to the happy chances of nature. Yet one must suppose that, if constant attention were not paid to masses of foliage like these, they would soon overrun everything, and turn what is now an ideal combination of architectural and natural forms into a featureless mass of green.

Haddon Hall, one of the most famous of the great country-seats of England, stands eight miles from the town of Matlock, in a very beautiful region of country, on a bold eminence on the east side of the river Wye, and not many miles from Chatsworth, the equally famous but more modest seat of the Duke of Devonshire. Haddon Hall, soon after the Norman Conquest, was owned by the Avenell family, from whom it passed to the Vernons. Sir John Vernon, who was called the King of the Peak from his magnificent scale of living and lavish hospitality, and who died soon after the accession of Elizabeth, was the last male heir of this family, and Haddon Hall passed, by the marriage of his daughter, to the Manners family, who were then the Earls and are now the Dukes of Rutland. It remained their principal seat until the beginning of the last century, when it was superseded by Belvoir Castle in Leicestershire.

To this fact is probably due its preservation in its old-time estate. No part of it is of later date than the sixteenth century, while the chapel shows the style of the reign of Henry VI., and the tower above the gateway is supposed to have been built in that of Edward III. The gallery, which dates from the time of Elizabeth, seems to be the portion represented in our picture. At this time the great terraced gardens were also laid out. The park, once very fine, was plowed up and put under cultivation about ninety years ago, but some fine groups of trees were allowed to remain in the vicinity of the house.

WE are glad to observe the persistent efforts which are put forth by some enterprising manufacturers of bicycles

to have on exhibition at the Columbian Fair samples of well-made roads, in order that the people may become thoroughly acquainted with their value and the method of constructing them. Of course, good roads would be an especial boon to the makers of these machines, but they would be of advantage to every man, woman and child in the country, and we do not feel inclined to refrain from a grateful recognition of the work by Colonel Pope and his fellows, simply because they, along with all the rest of us, would reap some benefit from an exhibition of this sort. The famous journey from Chicago to New York by relays of wheelmen did a great deal toward enlightening public opinion as to the quality of our roads, since it was proved that over all the route between the two cities there was practically no road whatever in first-class condition. Good roads would, without a doubt, increase the sale of wheels, but on the other hand it is probable that the invention of the bicycle and its rapidly increasing use, both for business and pleasure, will do much toward hastening the improvement of our highways.

Indeed, it seems unfortunate that, instead of trying to secure a small specimen of good road at the Fair, the effort had not been begun earlier, so that a much more important and imposing exhibition of good roads might have been secured. The suggestion is, of course, made too late, but, if the co-operation of the various state governments could have been secured, it would not have been impossible to have had one perfect road from New York to Chicago ready for use during the Fair. It is a long journey from this city to Chicago, but we have no doubt that if there was a good road between the two cities there would be thousands of tourists who would make the entire journey by bicycle next year, and, of course, there would be thousands more who would start from intervening places. If too late for this, the wheelmen at least ought to begin at once to agitate for a road between New York and Philadelphia, or between New York and Boston, built in the most approved way, and kept in absolutely perfect order from end to end.

IN a personal letter recently received, Monsieur Naudin, writing from the Villa Thuret, in Antibes, says:

Speaking of Oaks, I am making an experiment which will perhaps be useful to the Algerians, the grafting of the Chestnut on *Quercus Mirbeckii*, a common tree in Algeria. The grafts have succeeded in a marvelous manner so far at least.

Prunus Davidiana, of which you speak in GARDEN AND FOREST, fruits freely at the Villa Thuret. Here it is a vigorous tree which is not attacked by the insects or fungi which destroy our Peach-trees. We are going to plant the seeds to obtain stock upon which you graft the common Peach in the hope that the grafted plants will be less liable to disease and insect attack. The fruit is as large as a walnut, with very thin flesh, and is not edible.

Among Vines I have an interesting novelty, the first fruiting in France of *Vitis rugosa* (or *V. Coignetiae*) of Japan, a dioecious species. For a long time we only had male plants, but from seed received three years ago from Japan we have raised female plants which have flowered, and the flowers, being fertilized by insects have produced handsome bunches of grapes much earlier than those of the common Vine, which is just coming into flower. Later we shall be able to judge if these Japanese grapes possess any economic value.

Fairmount Park, Philadelphia.

THE pleasantest way to approach this noble pleasure-ground is from the suburbs of Philadelphia, for, until the projected boulevard from the City Hall buildings is completed, the rattling of one's bones over the rough pavements from the heart of the city is very fatiguing. The entrance from Germantown gives one, however, a delightful drive through that historic suburb, with its quaint old houses lining its main street, and thence through the more modern highways, bordered by handsome houses set in spacious grounds. Should one choose the Wissahickon way, he makes a détour through the most picturesque region within the confines of the park, or should he desire a more direct approach, a series of cross-country

roads will enable him to reach, in less time, the more formal section of the grounds. There are many points about Fairmount Park which give it exceptional advantages as a place of resort, and the admixture of formality with rustic wildness gives food for all tastes. The Wissahickon drive has always been full of charm for those who love the shaded banks of a tumbling stream, winding through dense foliage and bordered by picturesque rocks hung with vines and ferns, and this, to the lover of seclusion and country charm, will always be the loveliest and most delightful portion of the park. But, on the other hand, the great bridges overarching the broad Schuylkill, the thronged driveways along its willow-planted banks, the group of buildings that survive the centennial exhibition with their surrounding of formal flower-beds, and, added to all, the view of the huge city with its towers and spires, will be ever full of attraction for the general public.

These two rivers, the Schuylkill and the Wissahickon, are the distinctive feature of this park; the one giving to it an imposing effect, and the other an exquisite rural charm. The great railroad bridge that spans the larger stream frames pleasing pictures in its arches. Along either bank wind wide, smooth driveways thronged with carriages and pedestrians, while countless gayly painted boats of varying shapes and sizes add to the cheerfulness of the scene. The shores of the river show wooded capes and pleasant bays of foliage; the throng smiles and chatters; groups of laughing young people rattle by on bicycles. Now and then a little cavalcade of riders dashes along, and the whole effect is joyous and gay.

I note the generally cheerful aspect of the frequenters of American parks, in contrast with the bored and uninterested look of people in London and Paris, who take their perfunctory airing leaning back languidly against the cushions and looking neither to the right nor to the left. Here, people enjoy the parks; they smile, they sit erect, there is an air of exhilaration and happiness about them refreshing to behold. There is a certain infectious gaiety in the scene, as if the world took its airing because it desired the fun, and not simply to be in the fashion. This is very apparent even among the serious Philadelphians, who relax the gravity of their aspect when they drive, and seem evidently to rejoice in the bright air and quick movement of the changing scene.

Two buildings of the exhibition of 1876 are still preserved in the park—Memorial Hall, which serves as a museum of pictures and relics, and Horticultural Hall, which affords shelter for tropical plants and for other delicate things which are used for the summer adornment of the grounds. Around these two edifices formal gardening is befitting, and here I found, in April, thick gay beds of Pansies and Tulips and Hyacinths that filled the air with fragrance. It was too early for much foliage, but there was a shimmer of green amid the ruddy tree-tops of the woods. Cherry and Peach-trees were blossoming bravely, and the Willows were in early leaf, casting golden reflections into the streams over which they hung. The charm of budding spring breathed gaiety and cheer, and the whole effect of the park, thronged with people, was inspiring. The Philadelphians take pride and delight in their park, as well they may, for such an open tract of ground (2,800 acres) near a great city is a wonderful possession, and the story of its gradual growth from its original small size is full of interest.

It dates back as far as 1812, when the Philadelphians, desiring to obtain a supply of fresh water free from the impurities of city drainage, purchased the precipitous bluff known from earliest days as "Faire Mount" over Schuylkill, which was then considered a remote spot. The first purchase was of five acres, but gradually other land was acquired, so that as early as 1828 the whole quantity was twenty-four acres, for which about \$117,000 had been paid. After the water-works had been established on a scale unexampled at that time for magnitude and excellence, the good taste and judgment of the projector suggested the planting of trees and vines to hide the rugged rocks. At that time all the surroundings were rural; beautiful country-seats were situated on either bank of the Schuylkill, and there were no factories or villages along the river for a stretch of fifteen miles.

For more than twenty years Philadelphia reposed in the belief of the unsurpassable excellence and perpetuity of the Fairmount water-works, but at the end of that time it was rudely awakened to a consciousness that the ancient country-seats were being deserted, and that manufactories and villages were clustering upon the river-banks, and endangering the purity of the water-supply. With characteristic public spirit the leading men urged prompt action, and, in spite of the usual opposition always encountered by the advancers of popular improvements, they were able to accomplish their purpose. An opportunity offered for buying Lemon Hill, an estate of forty-five

acres, belonging in Revolutionary times to Robert Morris, the patriot financier, and later to a successful merchant of liberal taste, whose embellishments had made it the pride of Philadelphia as Pratt's garden. It finally fell into other hands, and a commercial revolution enabled the city to purchase it for \$75,000 to protect the water-works. But not as yet was this ground considered a park for the people. For twenty years more there was a struggle between public spirit and officialism, and not until September 28, 1855, was an ordinance of councils approved which "devoted and dedicated to public use as a park the Lemon Hill estate, to be known by the name of Fairmount Park."

Another tract of land of forty-five acres was tendered to the city in 1854 by some generous citizens; but, as such benefactions are often treated, it was received with reluctance, and two years elapsed before the conditions of acceptance were fulfilled by laying out avenues and walks to enable it to be used as a pleasure-ground.

In 1857 thirty-four acres more were bought by subscription and tendered to the city, and again this gift was stoutly resisted by an opposition that did not shrink from denouncing not only the action, but the motive of the donors. But at last the large-minded men carried their point, and the Sedgeley tract, which also was once the property of Robert Morris, was added to Fairmount Park, and the munificence of the donors was gratefully recognized by the reluctant city.

A reference to the old documents in the Philadelphia library shows Holmes' map, dated A. D. 1687, to contain a manor of nearly two thousand acres called Springettsberry, which contains Faire Mount. This manor, sold by the commissioners of William Penn, and passing through various hands, has most of its disjointed fragments reunited as one body in the eastern area of Fairmount Park. Many of the contributions for the two tracts given by subscription were of a most generous nature, ranging from \$1,000 to \$10,000, but the greatest number of them were in sums of \$100.

From this point there was less obstruction, the park grew in popular favor, and a large tract of land was bought on the western bank of the Schuylkill by four patriotic citizens, and then offered to the city at the reasonable price at which it had been obtained. This time there was no hesitation, and the noble estate of Lansdowne, containing over one hundred and forty acres, was secured for something less than \$85,000, being a smaller price per acre than was paid for any other piece of land bought for this purpose up to that time. In 1867 an act was passed by the General Assembly of the Commonwealth of Pennsylvania, with the entire concurrence of the city of Philadelphia, giving a right, title and ownership to the ground appropriated for public purposes to the city, and providing that it should "ever be maintained as an open public place or park, for the health and enjoyment of the people of said city and the preservation of the water-supply of Philadelphia." The act further provided a Park Commission, composed of certain city officials and ten private citizens, to be appointed every five years by the District Court and the Court of Common Pleas, and to them the care and management of the grounds were entrusted, as well as the plans and necessary expenditures for their improvement and maintenance.

In 1868 the Park Commission prepared a bill for the Legislature concerning the boundaries of the park, and at that time the total area prescribed by the Assembly amounted to 2,240 acres, to which two more public-spirited citizens, Jesse and his sister Rebecca George, members of the Society of Friends, added as a benefaction eighty-three acres of valuable land which had been the uninterrupted home of their ancestors for many generations, only reserving an annual payment to Jesse George of four thousand dollars by the city during his life, and one thousand to his sister, whose share of the property was one-fifth. This part of the park, in memory of the generous givers, is known as George's Hill, by resolution of the commission, in handsome acknowledgment of this munificent grant.

After consultation with Messrs. Olmsted and Vaux, of New York, and Mr. Robert Morris Copeland, of Boston, a still further extension of the park was urged by the committee, both for the preservation of the water-supply and for the accommodation of the rapidly increasing population, and it was suggested that the romantic scenery of the Wissahickon would form an addition of untold value to the beauty and usefulness of the park.

This suggestion of the committee was accepted, and a chief engineer appointed to carry out the work. Drives and walks were constructed, springs were improved and ornamented, thousands of trees were planted, and permanent park boundary monuments placed in position, new acquisitions of land were made, and the work progressed steadily, till in 1878

the land belonging to the park amounted to 2,791 acres, a larger acreage than that of any park in this country. In 1876 the park was the site of the Centennial Exhibition, and to provide for the buildings and other accommodations for so great a number of people, many topographical changes were necessitated. The buildings were afterward removed, with the exception of those mentioned above, and the grounds, as far as might be, restored to their original condition, though some of the modifications of the surface were permanent; but it is claimed that these changes were rather to the advantage than the disadvantage of the park. Not long since the house occupied by William Penn, during his life-time, was removed, brick by brick, and rebuilt within the park, where it is an object of much interest to visitors.

One of the men most closely associated with the organization of the park was the venerable Eli K. Price, who continued in his office of Commissioner till after the age of eighty, furthering its interests always with assiduity and wisdom. As Chairman of the Committee of land purchases he had much to do with the acquisition of the valuable country-seats that were incorporated in its domain, and his sound judgment in matters of business enabled the commissioners to purchase while property was low, so that, vast as was the expenditure, it was still reasonable compared to the actual value of the land acquired. Over seven millions of dollars were expended in the mere acquirement of the property, which shows the admirable public spirit of Philadelphia, which is always to be depended upon in matters of real moment. In a report written by Mr. Price in 1878, at the age of eighty, occur the following pregnant sentences:

"The worth of life to us all is to live it and prolong it in health and enjoyment, and it is by thus doing that we best show our gratitude to the Giver of life. Conceive of our approximate million, and coming millions, as being without Fairmount Park, can any human imagination begin to estimate the sum of human health and happiness that would be lost to Philadelphia, Pennsylvania, the world? Who could make the trial to run the parallel of the value of ten million dollars as the price of the park invested, and running at interest for the city, with the successive generations of her millions of people without the culture, and health and happiness of the park, and not feel humiliation, and without being shocked at the meanness of the suggestion. Money is a sacred trust indeed for its potency for good, but life, health, happiness, and gratitude to God are worth more than all hoarded wealth. We have and will keep this park; we will improve and love it; it shall be our pride and perpetual enjoyment; it shall be for us 'a thing of beauty, and a joy forever.'"

A city in the breasts of whose citizens beats so patriotic a spirit as this may well be proud of them, and of the boon they have received at their hands, and well may they glory in the magnificence of this immense park, with its forests of venerable trees, its stately and charming rivers, its picturesque glens, its fine old homesteads, where but the great Oaks survive, its splendid and varied outlooks, its wild romantic resorts, and rolling hills clad in verdure. There is a wealth of vegetation upon this rich well-watered soil that makes cultivation not so much a struggle with nature, as a work of pleasure in directing it, and the long existence upon the spot of many venerable groups of trees gives a dignity and permanence to the aspect of this fertile park that is lacking in those of more modern construction. Indeed, the middle states, with their longer season, their greater depth of soil, can boast of finer trees than New England shows, except in its most favored sections, as in the Connecticut valley, for instance; and the whole effect of Fairmount Park was to me most lovely and impressive even before the summer had clothed it with its greatest weight of foliage.

One can well imagine the relief of its cool shades to the citizen baked in the brick oven of the level city throughout the torrid heats of a Philadelphia summer, and bless the foresight of those wise and generous men who provided for them this gentle and cool retreat, which must mean life itself to millions in the future.

Hingham, Mass.

M. C. Robbins.

Midsummer Shrubbery in North Carolina.

IN a neighbor's yard stands the largest plant of *Vitex Agnus-castus* (the Chaste-tree) I have ever seen. It is fully fifteen feet high and twenty feet across the top. Just now it is covered all over with its clusters of blue flowers. The books all call the flowers of this shrub "pale lilac," and so they are under glass, but out-of-doors there is only the faintest tinge of lilac to distinguish them from pure blue, and at a little distance

the effect of the mass of bloom is clean blue. It is strange that more use has not been made of this plant here, as the tree I have mentioned is the only one I have seen in Raleigh. A profuse flowering shrub with blue flowers is a rarity at any time, and particularly at midsummer.

In strong contrast with the Chaste-tree, the double-flowered Pomegranates have been making a gorgeous display for nearly a month. The brilliant scarlet flowers, as large as an ordinary rose, scattered over the glossy foliage of a tree twenty feet high, have a very pretty effect. There is in Raleigh one large and old Pomegranate of the double-flowering sort that annually produces flowers running all the way from pure white through flesh-color, pink, white and scarlet striped, to the most brilliant entire scarlet. I saw last week a superb bouquet cut from this tree, which illustrated its sportive character well.

White Oleanders, too, have begun their all-summer campaign of bloom. The single white sort seems to be the hardiest, and stands our winters in sheltered places quite well, while the pink-flowered sorts are invariably badly killed back if not carefully protected. If allowed to make a mass of shoots from the ground it is easy to protect any Oleander through the winter here.

But the popular shrub just now is the Gardenia, or Cape Jasmine. The ladies wear great clusters, cut with long stems and glossy leaves, and at the railroad-stations crowds of boys offer the summer traveler huge bouquets of the fragrant white flowers for ten cents.

Of the hardier shrubs *Spiræa Billardii* is now the most attractive, with its feathery spikes of flowers, looking well on account of its rarity here. The great evergreen *Magnolia*, of course, is in bloom, and has been for a month. One flower, with its big shiny leaves, makes a bouquet and perfumes a whole room.

I am planning a mass of shrubbery in which the white Oleander is to be the centre-piece, *Vitex Agnus-castus* is to surround it and kept slightly lower, then Cape Jasmînes, all around, and on the outside, as a guard and shelter, a row of *Spiræa Billardii*. Massed closely in this way, and with Pine-boughs stuck around in winter, to keep off the winter sun and wind, I have no doubt that all will do well.

The big Coral-plant (*Erythrina crista-galli*), of which I have written heretofore, came through the winter finely under a mound of sawdust, and now has a top six feet high and as many through, and is a perfect glory of crimson bloom, being, beyond all comparison, in advance of plants lifted and wintered under the greenhouse benches. From the hard woody character of the stump of this plant I believe that this mode of winter protection might be adopted at the north by making the mound of perfectly dry sawdust, and then covering it with a water-proof shelter like one of the corrugated paper hay caps now used. The experiment is well worth trying northward. Old plants of the Jerusalem Cherry (*Solanum Pseudo-capsicum*), I think, could be wintered there in the same way. Here I have an old plant of this *Solanum* that has stood for years past under the south side of a building, keeping its load of scarlet berries until Christmas, and never entirely losing its foliage, which only gets singed for a few inches at the top. The roots of *Manettia bicolor* came through, too, with a dry cover. There is much to be learned yet in regard to winter protection outdoors of half-hardy plants, particularly in mild latitudes, and I shall continue to work in this line.

Raleigh, N. C.

W. F. Massey.

Some Interesting Plants.

THE other day the youngest member of the family, who had been on a botanical expedition, brought in some flowers of a trailing vine which he had found growing in our marsh. It had rounded heart-shaped leaves, and small five-parted and wheel-shaped flowers of a dull purple. These soon proved themselves unpleasant neighbors, as they emitted a strong, disagreeable odor like that of rancid oil. The plant was new to me, but it was plainly a member of the Milkweed family, and a botanical friend identifies it as *Gonolobus hirsutus*. We examined with interest the short ovate flower-buds of these comparatively rare flowers, the fleshy ring in the throat of the corolla, and the waxy masses of pollen. There were ten of these fixed in pairs to the five stigmas. The plant is allied to the climbing *Periploca Græca*, sometimes called Virginia Silk-vine, which is occasionally seen in gardens, and is not a native of Virginia, but of southern Europe.

A few interesting shrubs are now beginning to bloom. One of these is an early *Hypericum*, *H. patulum*, which is the earliest of the family to bloom here. This has showy yellow flowers of good substance, about the size of those of the familiar Mock Orange or *Philadelphus coronarius*. The plant is an

ornamental one, with large leaves for a *Hypericum*, and pretty pink stems. Our specimen was planted in the spring of 1891. It died down to the ground last winter, but is now growing vigorously and has many flower-buds yet to expand.

Another pretty and rather uncommon shrub is *Callicarpa purpurea*, which is a large bush with ovate-oblong toothed leaves, and clusters of small, light pink flowers, now in bloom. A striking peculiarity of this shrub is the fine yellowish dust with which the purple stems are sprinkled. The grains rub off at a finger-touch. They are ornamental, and, perhaps, some wise botanist has discovered their meaning and use, and how they are produced so freely. The foliage of this *Callicarpa* is a pretty shade of light green, contrasting well with the purple or plum-color of the stems and with the beginning of the midrib of the leaves, which is of the same rich color. The shrub is valuable in fall and winter for the metallic blue of its small polished berries, which remain upon the twigs until spring.

Another very pretty little plant, which is behaving quite as a well-bred plant ought to do, is *Abelia rupestris*. This is now showing a few very attractive trumpet-shaped white blossoms with small pink sepals at the base of the corolla. The flowers are delightfully fragrant. It has many buds, and will remain long in bloom. It is an evergreen here, with small varnished

Sander & Co. under the name of *T. Brymeriana*. It has white sepals and petals flushed with mauve, and a labellum like that of *T. Marshalliana*, with the addition of a dash of purple on the middle lobe. The two parents of this hybrid have lately been an attraction at Kew. No tropical Orchids are less difficult to cultivate, and not many surpass these *Thunias* in attractiveness when in flower, the dazzling snow-whiteness of the one and deep amethyst-purple of the other, the large size and abundance of the flowers on well-managed specimens, together with their lasting qualities, being all desirable characters in garden Orchids.

CATTLEYA PRINCEPS.—I should call this nothing more than *C. granulosa*, var. *Schofieldiana*, although its possessors, Messrs. Sander & Co., consider it distinct enough to merit a name. It has tawny yellow sepals and petals, blotched with purplish crimson, white side lobes to the labellum, and the midlobe covered with maroon papillose spots. The flowers are very large, and to some tastes very ugly.

CATTLEYA AMESLÆ.—This is a beautiful albino, much like *C. Warneri* in the size and form of its flowers, which are

Fig. 58.—The Terrace at Haddon Hall, Derbyshire, England.—See page 326.

leaves and pink stems. Its hardiness has not yet been fully tested here, but it has proved equal to the winters of Washington, where it has been for years, I am told, a conspicuous ornament of the public grounds. It has grown rapidly here since it was planted, and is in partial shade. It forms a neat small shrub pretty at all seasons.

Hollyhocks, Yuccas and Trumpet Creepers, on this second day of July, are still flowering very lavishly, and many late *Spiræas*, herbaceous perennials and annuals furnish us with an abundance of cut flowers. As yet we have had a favorable season, with no very dry weather, and the grass is still fresh and green.

Foreign Correspondence.

London Letter.

THUNIA VEITCHIANA ×.—This plant was raised in the Chelsea Nurseries from *T. Marshalliana* and *T. Bensoniæ*, and flowered in 1885, when it was named by Professor Reichenbach. The same cross was shown at the Royal Horticultural Society meeting last Tuesday by Messrs. F.

pure white, with a tinge of yellow in the throat. It was exhibited by Messrs. F. Sander & Co. at the last meeting of the Royal Horticultural Society, and obtained an award of merit.

SOBRALIA LUCASIANA, a variety of *S. macrantha*, with short stems, very broad leaves and flowers with white segments, the lip pale rose, with a yellow blotch in the throat, was awarded a first-class certificate, as also was *Cattleya Empress Frederic*, from Baron Schroeder's collection. This is a Veitchian hybrid raised from *C. Mossiæ* and *C. Dowiana*, and is characterized by white sepals and petals, a deep maroon-purple lip margined with a much paler shade, the whole flower being of exceptional size and beauty. *Dendrobium Souvenir d'Alec* is a white-flowered variety of *D. transparens*, and *Grammatophyllum Seegerianum* is what we have had already under several different garden names, but is probably *G. Fenzlianum*.

LÆLIA GRANDIS, var. *TENEBROSA*.—This magnificent variety of a comparatively mediocre species has recently figured largely at exhibitions in England. It is one of the most

attractive of all Cattleyoid Orchids, its huge flowers of a rich red-brown and maroon having few equals. Recent importations of this plant into England have made it comparatively plentiful in English collections, although it is still an expensive Orchid.

CALLA ELLIOTTIANA.—The whole of the plants of this new yellow-flowered Calla, or, as it should properly be called, *Richardia*, was sold by auction a week ago. It will be remembered that the plant was first brought into notice at one of the fortnightly meetings of the Royal Horticultural Society about three years ago, when it was awarded a first-class certificate. Since then Captain Elliott had increased the stock, by means of seeds and offsets, with such success that he was able to put up nearly two hundred and fifty plants for sale. These realized from seventeen guineas to about twenty-five shillings each, according to size, the total sum obtained for the whole being four hundred and sixteen pounds. The London nurserymen were the principal buyers. No doubt, in a few years this beautiful plant will be as plentiful in gardens as the white-flowered one is now. Evidently it is as easy to manage as the rest of the *Richardias*. I omitted to state in my previous letter that Captain Elliott's Calla was awarded the first prize for the best new plant in bloom at the International Horticultural Exhibition at Earl's Court.

CALLA PENTLANDII.—A plant bearing this name was exhibited at a meeting of the Royal Horticultural Society, held on Tuesday last, and from its being yellow flowered it attracted much attention. While it differs from *C. Elliottiana* in having a slightly larger spathe, and in being tinged with purple at the base inside the spathe, as well as in having unmottled leaves, it still bears a good general resemblance to that plant, and is probably another form of the same species, whatever that may be. The species of *Richardia*, at present known in gardens, are *R. Æthiopica* (*Africana*), *R. albo-maculata*, *R. hastata* and *R. melanoleuca*, and no doubt these two new yellow-flowered kinds are varieties of one or the other of these.

TREE-PRUNING was the subject of a lecture by the Director of Kew, Mr. Thiselton Dyer, at the last meeting of the Royal Horticultural Society. It is a fact that only very few people pay any attention to the proper manipulation of young trees intended to form ornamental specimens in parks and gardens. As a rule, a tree is allowed to grow as it likes after it is once planted, and as a consequence a large proportion of the trees one sees in gardens are unshapely, and sometimes even a source of danger. Tree-growers who understand their business are alive to the necessity of careful pruning from the nursery to the full development of the tree. Mr. Anthony Waterer declares that if properly managed all trees should be able to support themselves from the beginning, and to enable them to do this they must be prevented from making strong lateral growth until the trunk, or back-bone, of the tree has been formed. Mr. Dyer pointed out that, with few exceptions, height is the first desideratum in a tree, and to enable it to attain this the growth must be encouraged in the leader and kept within bounds in the lateral branches. In shallow soils most trees have a tendency to become mop-headed. Like root, like top, is the rule that controls tree growth. In deep soils there is less need of pruning, but in all soils it is necessary to watch the development of the trees, and prevent such growth as would throw the specimen out of balance. Of course, the cultivation of trees for timber is one thing, whereas that of trees intended for ornamentation is another. But all trees require to be looked after and kept shapely from the first. The way to prune and the way not to prune were pointed out by Mr. Dyer, and the value of coal-tar and carbolic acid as a dressing for tree-wounds was testified to by the good results obtained by its use at Kew.

ROSE CRIMSON RAMBLER.—This is a rich crimson-flowered bunch Rose of very great promise, of which Messrs. C. Turner & Sons, Slough, hold a large stock. It was obtained by them, indirectly, from Japan, and was certificated

two years ago by the Royal Horticultural Society, under the name of "Engineer." Mr. Turner says it is one of the freest Roses he knows, and the long, sturdy branches, large, healthy foliage with huge bouquets of compact blood-red flowers on the specimens he exhibited last Tuesday, bore out this statement. The plant is one of the many forms of *R. multiflora*, and is probably the very best of these as represented in English gardens. The general verdict with regard to it at the Royal Horticultural Society's meeting last Tuesday was that it was a Rose of quite exceptional merit.

The exhibition of Roses held last Tuesday was remarkable for the number of beautiful cut flowers of Tea Roses, and also for the collection of Sweet Brier hybrids exhibited by Lord Penzance, to whose sagacity and skill we are indebted for these beautiful Roses. By crossing the common Sweet Brier with various kinds of garden Rose, Lord Penzance has obtained an entirely new break, for while the flowers still retain the charm of form of the Sweet Brier-blooms, they have gained in substance and in variety of colors from the other parents. Thus there are many shades from pale blush to deep crimson, and a few of the kinds are semi-double. The leaves are almost as fragrant as those of the Sweet Brier.

HERBACEOUS PÆONIES have lately received special attention in England. Chiswick has now a large collection of named varieties obtained from all the best growers, and a committee of experts met there recently to judge them. Great improvements, both in form and color of the flowers, have been made by recent breeders of these plants, and they are consequently becoming generally popular. Herbaceous Pæonies have all the good qualities of first-rate border-plants, and scarcely any bad ones. Planted in good, deep soil, and let alone, they will form strong clumps in a year or two, and when in flower they make a grand display. One of the lawns at Kew has this year been given up entirely to large beds of Pæonies, and although the plants are too small to make much display, yet they already show promise of developing into a most effective garden. The named varieties are endless. In planting, it is advisable to pay some attention to the grouping of the colors, or harsh combinations will probably occur. The best of those which received the premier award this year at Chiswick were as follows: White—Queen Victoria, Duchesse de Nemours, Grandiflora nivea plena, Neomie Demay, Virginie, Madame Montigo, Albiflora Whiteleyi. Pink—La Voluptuese, Modeste, Camille Lemoine, Madame Ducel, Eglais Adanson, Lutitiana, Madame Jules Calot, Comte de Nanteuil, Lilacina grandiflora, Furtado, Miranda, Charles Binder. Crimson—Edouard André, Rubra triumphans, Paul de Ritert, Madame Mechin. Yellow—Canari, Sulphurea, Prolifera tricolor, Flavescens.

Notes on Shrubs.

WITH the beginning of July there is a very marked decrease in the number of our shrubs in flower, and every one which comes into blossom after that time possesses more than ordinary value, because the great majority of trees and shrubs have ceased flowering by the end of June.

One of the most conspicuous shrubs in blossom in the last days of June and early in July, in this vicinity, is the tall *Deutzia scabra* in its several forms. Although an introduction from eastern Asia, this species is an old inhabitant of our gardens, and, like the earlier-flowering dwarf *D. gracilis*, it has not been much modified or very greatly improved since it was brought to European and American gardens. There are, however, a number of named forms in cultivation, none of which can be called remarkable as distinct or as improvements over the standard single and double flowering kinds. This *Deutzia* has been received at the Arboretum under a number of specific names, such as *D. Sieboldiana*, *D. Japonica* and *D. crenata*, with their varietal designations appended, but all are unmistakably *D. scabra*. The single-flowered plants, which are very easily raised from seed, often show a considerable difference

in the size of the blossoms, the petals in some seedlings being much larger, and therefore more showy, than others. There are forms in which the buds, and, after expansion, the outside of the petals, are of a deep pink color. A plant received from England as *D. scabra candidissima* cannot be called any finer or whiter than the ordinary forms. The *D. candidissima* flore pleno of some American nurseries is simply a double white-flowering *D. scabra*. A well-known American firm has sent out a fine double form under the name of "Pride of Rochester," which has longer petals than some others, and has pinkish buds. There are, however, only twenty petals to each flower, so that the centre is somewhat open and plainly shows the pistils. In other variations the petals are more numerous, thirty being a common number, and as they are more crowded the blossom spreads out wider and has more of a compact rosette character. A good form, with these full double flowers, has been sold as *D. Watsoni*. As is the case with so many other cultivated plants, there is a monstrous form of this *Deutzia* which has variegated foliage, the leaves being blotched or mottled green and white. While it is odd, it cannot be called pretty, and, like most other variegated plants, it should not be planted except as a curiosity. These variegated leaves are often more or less misshapen, and are liable to revert to the green form, their normal healthful condition. Any peculiarly striking form of this *Deutzia* may be propagated by layering, or on a larger scale by cuttings of ripe or green wood. As they usually bear fruit in abundance, the amateur may raise any number of plants from seed and retain such as produce the best bloom.

Both the early and late flowering *Wistarias* have generally quite passed their flowering stage, although the early-flowering Chinese *Wistaria* bears a few stray and poor racemes of flowers on its new growths. Our American species, the late-flowering *W. frutescens*, is ordinarily quite out of blossom by this time (July 2d), but there is in the Arboretum collection a variety or form of it which is still quite showy. This was received several years ago from the Messrs. Parsons under the name of *W. frutescens magnifica*, and it differs from the common type in having racemes which are sometimes over a foot in length, whereas in the common well-known form the racemes are usually very short and the flowers clustered. The flowers of this *Magnifica* form are large, of a pale purple or lavender color, and at this time the apical ends of the racemes, for about half their length, are still covered with flowers and flower-buds. It is not generally known that there is a white-flowered form of *W. frutescens*, which, like those of the type, has its blossoms in short compact clusters.

Visitors traveling to the sea-shore resorts north of Boston are at this season charmed and delighted with the bright yellow covered hills in the vicinity of Salem and in other parts of Essex County. The blossom which makes this handsome show is that of the Woad Waxen, or Dyer's Broom (*Genista tinctoria*), which now covers hundreds of acres in this part of Massachusetts, and has become established, in a small way, in other localities and places. Once established, it is likely to become a troublesome weed, and wherever it is introduced as an ornamental plant it should be looked after, that it does not get too commonly wild. Here it appropriates the surface of the soil to the exclusion of almost every other kind of vegetation, and seems thoroughly at home. The foliage, when in good condition, covers the ground with a glossy deep green, the stems being from one to two feet high, and when in blossom the whole surface of the ground, when viewed at a little distance, appears covered by a bright yellow carpet.

It is believed by many that the Woad Waxen was first introduced from Europe by Governor John Endicott, who brought it to his garden, at Salem, Massachusetts, in the first half of the seventeenth century. It was probably brought over for the beauty of its yellow blossom, although sentiment may have been the chief motive; or, what is not at all improbable, it may have been introduced and purposely allowed to become wild, with the idea that it might be of use to the colonists for the yellow colors to be obtained from its stems and branches, for which purpose it was extensively used in the mother country.

The Woad Waxen in the Arboretum is liable to suffer from two or three diseases, which injure it very much at or after blossoming time. A species of *Aphis* is sometimes very abundant on the young shoots, dwarfing the growth, and, by the excretions of the insects, causing the plants to have a grayish appearance at blossoming time. About this season the leaves also often turn dark brown or black and fall, apparently from the effects of some attack by fungus. A large ashy gray-colored, so-called Blister-beetle (*Macrobasis unicolor*) is also extremely fond of the leaves, and often occurs in such numbers as to

quite strip the plants of foliage before midsummer. These beetles also greedily devour foliage of the Honey Locust and other plants of the Pea family.

Arnold Arboretum.

J. G. Jack.

Garden Carnations.

THE Carnation in its many varieties, not the florist's type, divided up into several sections according to the disposition of color on the petals, but the robust, free-blooming self-varieties, by force of decided and distinct colors, creates a rich effect in the garden. During the past few years much interest has been taken in the Carnation in England, not regarded from the strict florist's point of view, but simply as a garden-flower—free, robust and showy. The florist's kinds, the Bizarre, Flaked and Rose sections, fail through their want of decided effect. The kind of coloring is not distinct, and a bed of the most expensive varieties is not so beautiful to look upon as a mass of such a fine flower as the rich self-Kelton Rose or the lovely Comtesse de Paris, with a flesh-tone as delicate and refined as the most ardent lover of soft shades could desire.

There was need of much improvement in existing kinds of Carnation, self-colored it is true and often very beautiful, but the flowers lacked one essential quality in a typical garden variety—that is, a sound calyx, a calyx that keeps intact even during a period of wet weather. Those that burst the calyx are practically valueless, the petals tumbling about in hopeless confusion, unkempt and unsatisfactory. This is an important point, not only for the value of the flowers for the garden but also for cutting. A variety that carries its bloom in free clusters, with an entire calyx, and sends up a succession from the younger growths is of great value, both for supplying bloom for the house and for enriching the bed or border. There are certain indispensable qualities in a garden Carnation: (1) the flowers should be of a solid color, decided, rich and telling; (2) the calyx must not split; (3) the plant must have a robust habit, the growth vigorous, and (4) it must have fragrance. The first two points I have already made allusion to, and it is scarcely necessary to urge the impossibility of getting satisfactory plants if the varieties selected are of weakly growth. Few plants are more miserable in aspect than a sickly Carnation, and unless provided with an abundance of sturdy, healthy foliage it is useless to expect good effect or obtain shoots for layering. It seems strange that, notwithstanding the precious gift of fragrance to the Carnation, the delicious perfume of the old crimson Clove, or of its white counterpart, that this delightful attribute has been often overlooked. Varieties practically scentless are praised, but they lose much in value when deprived of one of the greatest charms of a Carnation. Scentless Roses abound, and yet are retained in cultivation through exceptional form or color.

The smooth-edged flowers make the finest color-effect; but quite as attractive, in their way, are the fringed varieties, the uneven edged imparting a certain charm. One of the most delightful garden varieties I can call to mind is Raby Castle. The flowers are not remarkable for breadth of petal or what may be called robust expression, but the color, a kind of bright pink with a trace of salmon in it, is very effective in a mass. The fragrance is moderately strong, and the petals fringed. It blooms with the greatest profusion, produces an abundance of foliage, and may be made use of for forming broad edgings to walks, or, at least, borders, with the full assurance that it will please. This is the kind of Carnation that should be encouraged. A large, finely developed flower, broad in the petal, full, and robust, is a first consideration.

A lovely Carnation is Comtesse de Paris, which we have many times seen in fullest perfection. It is one of the most delicate in color, a tender blush, the flowers of exceptional form and delightful shape, and carried freely on sturdy stems, the foliage of great vigor. The calyx does not split, and there is another great feature, the plant sends up a succession of spikes, thus continuing the season long past that of the ordinary kinds. This is a point of great importance. We have here a forerunner of a race that will last in bloom until the season of frosts.

The great desideratum is to raise seedlings possessing the merits alluded to, and some varieties come very true from seed. A very striking new variety is called the Queen, sent out only last year by Mr. Charles Turner, of Slough, and raised from continental seed. The color is rich, clear and decided rose; the foliage very strong; habit dwarf, robust, and not drooping, and the calyx very firm.

A successful English grower of the Carnation recommends, as a top-dressing, soot and wood-ashes, as wireworms, a great pest, dislike them. Use manure sparingly, as some of the

most splendid displays I have seen have been in light, sandy soil, almost sea-shore sand, in full exposure to the ocean, the plants appearing to relish the salt spray.

Kew.

V. C.

Hardy Herbaceous Plants.

THE theory that the colors of the flowers of certain genera were limited received a severe blow when the scarlet Larkspur (*Delphinium nudicaule*) was discovered in California some years ago; and still later when the yellow *D. Zalil*, from central Asia, produced quite a sensation. The latter species, however, is only an annual, or biennial at best, and is likely to be superseded by the newer *D. Przewalksyannum*, which is a true perennial, and perfectly hardy, having stood the winter here unprotected. The leaves are orbicular-peltate, handsome. The spike is branched, about five feet high. The flowers are small, but abundant, sulphur-yellow, with short, scarcely spreading sepals lined with black hairs, and anthers black. The spur is long, straight and abruptly pointed. This species comes from central Asia, a region which, as yet, has been very little explored. For nearly all recent introductions we are indebted to the late Dr. Regel, to whose kindness and generosity a large army of correspondents can testify.

Cimicifuga racemosa is a strikingly bold and handsome border-plant, a native of the United States. It would make an elegant lawn specimen, fit to rank with *Eulalias* and other tall grasses for this purpose. The leaves are broadly triternate, with serrated margins like those of *Astilbe Japonica*, but with a spread of a foot or more. The compound spike is clothed for eighteen inches of its length with small, white, saucer-shaped flowers, which last a long time in good condition. The flower-stalks stand fully three feet clear of the foliage, stiff, erect, and without the least need of a stake. When out of bloom it is never unsightly. It may be raised from seed, which, however, needs more than a year to germinate, or by division, but it is very slow to establish itself. The specimens to which I have reference have required three years to attain the perfection of the original plant before it was divided.

Of the many border Catchfly-plants the scarlet *Lychnis Chalcidonica* excels them all for general usefulness. The brightness of its flowers attracts the eye from a considerable distance. It is very hardy, and is more or less in bloom from June until frost. The flower-heads resemble those of the common Sweet William, and the plant is just as easily raised from seed, and will bloom the first season if sown early. There is a double variety, also in bloom, but it is not nearly so robust as the single form.

Bocconia cordata is a well-known border plant, although somewhat despised, on account of the rapidity with which it spreads, crowding out almost everything but the coarser Sunflowers; and, from the fact that when once established it is hard to get rid of. When properly used it is an effective plant, and here we find it very serviceable with tall Sunflowers, *Silphiums* and New England Asters, as a screen for a by-path leading to the house. It is a native of China, and belongs to the Poppy family. The leaves are heart-shaped, with deep round clefts, glaucous green on the upper surface, and almost white beneath, which makes a very pretty effect when there is breeze enough to turn them over. Small white flowers terminate the stems, arrayed in a plume-like panicle. It is easily propagated by cuttings from the axils of the leaves or by division of the roots.

Campanula latifolia, var. *macrantha*, as it now appears with large pendent bells of blue, reminds me of the large plants of this species at the old Botanic Gardens, at Hull, England. Not all *Campanulas* are vigorous enough to endure our winters well. Many live through, but scarcely recover sufficiently to make any progress during the succeeding summer. At Hull there were large old specimens seven feet high, the clumps at the base measuring two or more feet across. *C. Van Houttei*, a very handsome garden hybrid, lives along and blooms sparingly, but never does justice to its reputation. In *C. Pallasii*, now in bloom for the first time here, we have a plant of promise, since every specimen came up after the winter with increased vigor. The leaves are ovate-cordate, with sinuated margins. The plants grow from two to three feet high, and make nice bushy, self-supporting specimens. The flowers are about two inches long by nearly one inch in diameter, violet-purple and pendulous; it is easily raised from seed. The variety *Speciosa* of *C. glomerata* is a most satisfactory plant, being thoroughly hardy. It grows about two feet high, bearing terminal and axillary heads of bright blue flowers, and lasts in bloom from June to September.

Astragalus Monspessulanus has been in bloom for a month, and is the most ornamental of all the alpine Milk Vetches in

cultivation. The stem is very short, with prostrate branches. It seldom grows more than nine inches high, and is covered from spring until autumn with handsome, hairy pinnate leaves. The flowers appear in dense prostrate racemes, reddish purple, changing to violet, and continue two or three months in bloom. It is a native of south Europe, and is best raised from seed.

The hoary-leaved *Veronica incana* makes an excellent rock-plant, and is attractive in or out of bloom. It is often effectively used in border-lines for the front rank. Flowers blue, in short spikes.

Geranium sanguineum cannot be too much recommended to all those who love a plant which "blooms all the time." From June until September this is bright with its salver-shaped, rosy violet flowers, and combined with abundant neatly orbicular-peltate leaves, it never looks untidy.

That giant among the Heron-bills, *Erodium Manescavi*, succeeds well here, and is another of those plants which are more or less in bloom the whole summer long. The stems are short or prostrate. The flowers are rose with deeper shades, and are produced rather stragglingly, but its handsome, hairy, fern-like leaves, often a foot in length, alone would commend it. *E. macradenum* is a more modest little species, having short stems clothed with elegantly divided foliage. The flowers are white with purple veins, and not unlike those of a small fancy *Pelargonium*. It is a native of the Pyrenees, and may be increased either by seeds or cuttings.

Helianthemum vulgare, the true Rock Rose, with several other species, mostly European, has given us some beautiful hybrids, ranging in color from white through all shades of red and yellow. They are low shrubs, and are more or less in bloom the whole season.

Oenothera Missouriensis bears surprisingly large flowers for a plant so modest in appearance, compared with many other members of this genus. Neither are its flowers so partial to shade as those of many of its relations commonly known as Evening Primroses, since their flowers open only in the evening. It is altogether a desirable plant, and is most effectively placed where its trailing stems can hang over some rocks.

A few seeds of a much improved form of *Dianthus armulatus* were sent me last year. Although this is one of the parents of the beautiful border Pinks, the type in a wild state gives surprisingly small flowers. These improved varieties, now in bloom, are, however, large and handsome, mostly of soft pink shades, but all have the darker ring formed by a blotch at the base of each petal-lob.

Wellesley, Mass.

T. D. H.

The Water Garden.

NYMPHÆA *Marliacea albida* is a hybrid Water-lily now bearing flowers which seem to be of the first-class in size and beauty. The petals are narrow and more numerous than those of *N. alba candidissima*, and they are of a translucent silvery white instead of opaque, as in that variety. The flowers are fragrant and freely produced, and altogether very distinct.

N. Marliacea carnea is the lightest colored of pink Pond Lilies. The flesh tint is of the clearest and most delicate shade. Nothing could be more exquisite than a half-opened cup-shaped flower in which the charming color is concentrated and relieved by the golden petals. The form is that of *N. alba*. When the flower is fully open the shade is of the faintest.

N. odorata Carolinensis is a very large full flower of the *N. odorata* type, with a suffusion of pink. My flowers of this plant have as yet failed to give the full coloring of those grown by Dr. H. T. Bahnson, with whom it originated, and, I presume, some difference of soil in which it is planted may be the cause of this.

N. gigantea is an Australian species now in flower. This is a tropical Nymphæa, and not to be confused with *N. odorata gigantea*, under which name a large-flowering form of our native Pond Lily is being offered. *N. gigantea* is probably one of the handsomest of Nymphæas, the color being a satiny-blue shading to white, with yellow silk-like stamens. The flower is carried above the water on a stiff stalk, and is about the size of those of *N. Zanzibarensis*. The leaves are dentate, green above, and bright purple beneath. From its Antipodean origin this plant would naturally flower in the winter, and it seems a difficult one to start, as it needs warmth. It is said to be impatient of root-disturbance. My tubers started up several times, and for no visible reason as often dropped their leaves. It may be well to say that for the opportunity of flowering this I am indebted to a friend, several hundred miles away, who sent me a strong plant already established. I mention this to

show (the plants now growing strongly) that *Nymphæas* may be safely transported, when moving, without injury.

Nymphæa candida is a white-flowering species from Bohemia. This seems of second size, but very free-flowering. The flowers are rather incurved at the tips of petals, which are of medium width. The color might be compared in purity and tone to that of the Snowdrop.

N. odorata sulphurea, somehow, has failed to secure the vogue of *N. chromatella*, but it has a charming flower of a sulphur tint, with light golden stamens, distinct, and well worth adding to the best collections. It has slightly narrower petals of less substance than *N. chromatella*. The leaves are maculated brown above, and thickly spotted with blood-red under.

The prevailing cool nights and frequent rains have not furnished the very best conditions for the growth of the tropical *Nymphæas* this season. The same conditions affect the hardy ones, though more slightly. These latter seem, however, to require more care in planting than the tender ones, which seldom fail to grow away strongly, while if the rhizomes of the hardy kinds are too deeply covered, or are not satisfied with their compost, they are apt to make very little progress. They also seem to resent shading and drip from other plants. The *Nelumbiums* seem especially particular in their requirements as to proper planting. If they are under proper conditions, few plants make more rapid and satisfactory growth, yet slightly different ones will cause them to halt. Of my two clumps of these, both planted on the same day in the same apparent mixture of soil, one has numerous large leaves and several buds, while the other is only now putting out a few small floating leaves. They are in different tanks, but have the same exposure, except that the slow ones are slightly shaded and receive a drip from an *Eulalia*. As in other garden-plants, apparently very slight conditions make the difference between success and failure.

Elizabeth, N. J.

J. N. Gerard.

Armeria vulgaris.—A delightful margin to walks, beds and borders is one formed of the common Thrift. It is a very hardy plant, the growth even, of a refreshing green color, and preserving its charming character the whole season, but, in addition, during the month of June there is a wealth of flowers that make an even surface of rich rose, distinct, decided, and beautiful. The effect of the Thrift thus used is to alter for the good the whole complexion of the garden. Its hard lines are toned down, and in the month that we long for flowers they are supplied in plenty. Edgings formed of this sea-shore *Armeria* last in full beauty about four years, but after that period it is wise to lift the plants, divide, and make a fresh planting. At first, the plants, which should be put in tufts a few inches apart, have not a very agreeable appearance, but they soon fill their allotted space, and then we have a soft cushion of growth, pleasant to the eye. Soft stone, with various pretty creeping plants allowed to run over them, is excellent for an edging, and for the sake of variety one may use the dwarf *Phloxes* and such things as the *Gentianella*, very beautiful where it can be induced to grow and flower with freedom.

England.

Correspondence.

Roan Mountain—A Summer Resort.

To the Editor of GARDEN AND FOREST:

Sir,—To some of your readers Roan Mountain is perhaps still unknown, although the summit, which is within thirty hours' ride of New York, is one of the most beautiful spots in America, and offers opportunities to lovers of nature which no other place of easy access to the people of our northern cities equals. Roan Mountain, which is one of the highest of the Appalachian peaks, is situated eighty miles north-west of Asheville, in North Carolina, the boundary between that state and Tennessee crossing its summit. It can be reached from this city by an agreeable and easy journey. The quickest and most picturesque route is by Philadelphia, Harrisburg and the Cumberland and Shenandoah valleys; in Pennsylvania and Maryland the traveler passes through one of the best-tilled and richest farming regions of the continent; just before the Potomac River is crossed, he passes over the battle-field of Antietam; in Virginia he can break his journey at Louray and explore the caves which have made this place famous. The accommodations here are excellent. A second stop can be made a few hours further south at the Natural Bridge, one of the marvels of America, and unsurpassed as a single object, independent of other features of striking beauty. Passing from the valley of the Shenandoah, the route enters that of

the upper James, a region of fertile fields, low, well-wooded mountains and picturesque scenery. The cars are changed at Johnson City, in east Tennessee, once notorious for the badness of its hotel, but now a booming town with an electric railway, brick blocks, a magnificent new hotel, and all the push and go of the "new south."

Here, the traveler leaving the East Tennessee, Virginia and Georgia Railroad embarks on a narrow-gauge road built to bring the iron ore from the famous Cranberry mines situated at the foot of the Roan. Its way for twenty miles is up the broad valley of the Watauga River, a tributary of the Holston, which flows out from the western slopes of the Blue Ridge; then it swings to the south and traverses Happy Valley, whose fertile soil a hundred unmanured crops of corn have not exhausted. This is the first valley in Tennessee settled by whites; here is still to be seen the remains of the first block-house built to afford defense against the Indians; here is still standing the tree under which the first court was held in Tennessee, and not very far away are the ruins of the first iron furnace established west of the Alleghenies. Gradually the valley narrows and the road-bed is carried along the borders of Doe River, a tumultuous mountain stream, which heads high up on the flanks of the Roan. In picturesqueness this part of the journey is not surpassed by that of any other rail route in the country; at one place, the stream tumbles through a narrow gorge at the foot of precipices hundreds of feet high; at others, its rocky banks are clothed with tall Hemlocks, shading vast thickets of the great Bay (*Rhododendron maximum*), which grows here with a luxuriance and splendor which astonishes the traveler unfamiliar with the Appalachian forests. Here twenty years ago he could have seen these forests in all their magnificence and Nature's supreme effort in forest-production, for in the number of species of which they are composed, and in the size and beauty of individual trees, these southern forests surpass every other deciduous forest of the earth. But the magnificence of the forest of the Doe River valley is a thing of the past; twenty saw-mills and a dozen tanneries strung along the line of the narrow-gauge railroad have done their work effectually. First the Black Walnuts went, and then the Cherries, for which this valley was famous. When these were consumed, the lumbermen turned their attention to the Yellow Poplar (*Liriodendron Tulipifera*); their work has been done thoroughly; stumps of this tree seven or eight feet across are common enough, but the big trees are all gone. Now they are cutting White Oaks, and the Hemlocks for tan bark. Large Hemlocks, however, can still be found near the streams, and on the first bench above the river stand as fine Chestnut-trees as can be seen on the continent.

At Roan Mountain Station the rail is left and the journey to the summit of the mountain is made over an excellent road. The distance is only twelve miles, the summit being easily reached in four hours. The ascent is of peculiar interest to the lover of trees, who will see a great variety and many noble specimens. At the sheltered base of the mountains, *Magnolias* abound, and then the road winds upward gradually from these and their relative, the Tulip-tree, through White Oaks and Chestnuts, Lindens and Red Oaks, Buckeyes, Birches, Sugar Maples and Hawthorns, until, as the upper limits of the forest are reached, its conspicuous features are the Black Spruce, the Balsam, the Striped Maple, the Mountain Maple, the Beech, the Yellow Birch, and the Mountain Ash, that is to say, the inhabitants of the sub-arctic forests of North America. In this short drive, therefore, of twelve miles, are to be seen trees which, at the sea-level, are scattered through more than ten degrees of latitude. On the western slopes of the Big Smoky Mountains in Tennessee, individual trees are, perhaps, larger, and the number of species rather greater than in the forests of the Roan, but in no place easily accessible to travelers unaccustomed to rough mountain travel can the Appalachian forests be seen so well as on this mountain.

If the journey is made, as mine was, in the last days of June, a wonderful sight awaits the traveler as he emerges from the forest on to the long grassy summit for which Roan Mountain is famous, for at this season the Mountain *Rhododendron* (*R. Catawbiense*) is in bloom. The summit is in the form of a saddle several miles long, the extremities being formed by two elevations of about equal height (nearly 6,800 feet); up to the edge of this open space the advance of the forest is pushed in irregular outposts, sometimes in narrow lines, and sometimes, where the shelter is better, in solid blocks of a few acres in extent. Along the borders of the forest, sometimes scattered individually, and often in broad masses, covering hundreds of acres, the *Rhododendron* grows mixed with bushy plants of the Mountain Alder (*Alnus viridis*).

No one can judge of the extent of the Rhododendron-fields on this mountain, for the scale is so vast that the eye cannot estimate areas; certainly there are spots on the summit from which thousands of acres covered with Rhododendrons and Alders can be seen at once. The thickets are impassable except where bears and cattle have forced tortuous trails among the bushes which ten days ago were covered with flowers; these are nearly all of one color, deep rosy pink, very similar in shade to that variety known in gardens as *Roseum elegans*, although an occasional plant with darker flowers can be found. An examination of the conditions under which Rhododendron Catawbiense thrives in its home on this mountain will show the treatment its hybrid descendants require in gardens. The soil where the plants are growing, and, indeed, over nearly the entire summit, is rich black vegetable-mold, varying from eighteen inches to two feet in depth; although saturated with moisture, as small springs are common, the surface-soil is perfectly drained, being underlain by coarse gravel filled with large stones. Abundant atmospheric moisture, for rarely a day passes without clouds settling over the summit of the Roan, increases the vigor of the plants; on the open slopes they rarely grow more than four or five feet high, but when protected by the Balsams (*Abies Fraseri*), specimens twelve to fifteen feet high are not uncommon. These natural conditions seem to indicate that Rhododendrons of the Catawbiense blood require rich, moist, well-drained soil, constant atmospheric moisture and protection from high winds, and that grown under such conditions they can support excessive winter cold as the temperature on the summit of the Roan has been seen to fall, in winter, to 30 degrees below zero of Fahrenheit, while ice probably forms during every month of the year except in July and August.

But the Rhododendrons do not offer the only attraction of Roan Mountain. The views from it are superb. A break in the mountains immediately to the west opens to the eye all the Cumberland system of middle Tennessee; to the south lies in full view the Black Mountain range culminating in Mt. Mitchell, the highest land in North America east of the Rocky Mountains; just to the right of the Black Mountains, Pisgah, a hundred miles away and twenty miles beyond Asheville, stands up boldly and alone, while beyond it, in shadowy outline, appear the high peaks of the Smokies. To the east of the Roan the broken masses of the Blue Ridge are in full view; to the north-east Grandfather raises its massive dome, and to the north the eye, looking out over a sea of smaller ranges, is carried into Virginia and West Virginia. The panorama includes eight states, and, owing to the isolated position of the Roan, is not equaled by that obtained from any other Appalachian mountain.

Many summer days may be pleasantly passed in wandering over the summit of the Roan, in admiring the ever-changing views, in exploring the wild flowers which cover its slopes and cliffs, or stretched on the soft masses of the Sand Myrtle (*Leiophyllum buxifolium*, var. *prostratum*), most delightful of the high Appalachian under-shrubs and the softest of beds, in studying the aspects of the forest, with its countless tones and shades, or in watching the eagles soaring high over the cliff which bears their name. The atmosphere is cool and bracing, the temperature rarely rising to seventy degrees, Fahrenheit, in the middle of the hottest days; the nights are always cool, and black flies and mosquitos are unknown. A residence on the summit is said to be a certain cure for hay-fever, and last, although not least, the accommodations in the Cloudland Hotel, built in the depression of the saddle at an elevation of a little more than 6,000 feet above the level of the sea, are excellent.

Leaving the summit of the Roan several roads are open to the traveler. If he is in a hurry to return to the north his quickest way is by Johnson City and the Shenandoah Valley. If two or three days more can be devoted to mountain travel he can descend to Roan Mountain station, continue up the narrow-gauge railway to Cranberry, and then ride through the mountains by the new settlement at Linville to Hickory, on the Western North Carolina Railroad. Another route is by Bakersville, on the North Carolina side of the mountain, now reached by a rough trail from the summit, and then by road through a picturesque region to Marion, a long day's ride, or by a road directly into Asheville, a longer and less picturesque journey of seventy miles. It must be remembered that the roads in all this mountain region are bad, and sometimes almost impassable for wheels, and that it is less fatiguing to ride than to attempt to drive. Pack-animals are little used or understood, and it is better not to attempt to carry any luggage that cannot be packed behind the saddle.

The mountaineers are uniformly kind and hospitable, and

do all that they can to make the traveler comfortable, but their manner of life is very primitive, and a "pone" of corn-meal, a dish of honey and a pitcher of buttermilk often exhaust their supplies. If this seems too simple fare, or the fatigues of a journey in the saddle are too great, one can see what is most beautiful in the Appalachian country, and get an excellent idea of the Appalachian silva from a visit to Roan Mountain, a journey which is not more difficult or fatiguing than a trip to the Catskills or the White Mountains.

Periodical Literature.

The Forms of Trees.—II.

LAST week we quoted part of a paper on this subject, which was read before the California Academy of Science by Mr. Gustav Eisen, in which the influence of wind and snow was chiefly considered. The following is a continuation of the same paper, in which the effects of sunlight and heat upon the forms are discussed:

"Another important agency in shaping the forms of trees is the direct sunlight and heat. As the force of the direct rays of the sun is different in different places, it follows that their effect upon trees and shrubs must vary with the locality as well as with the physiological structure and nature of the plants. Various other agencies, such as the moisture in the air, the force of the wind, the rainfall, dews and fogs, combine with the sunlight and heat, either in decreasing or increasing the effects. It is especially in warm and dry regions where the heat and light are all-powerful in modifying and directing the development of the form of a tree or shrub. An excess of heat and light is nearly always hurtful, and may even be so injurious as to kill the trees, or make them unfit for the region. It is especially the horticulturist that notes these effects of heat and light. In tender plants the effects are more pronounced and principally of two kinds. The direct rays of the sun injure the stem or trunk on the south-west side, or on the side on which the greatest force of the sun-rays are concentrated during or shortly after midday. The tender bark and cambium are scorched, dry up and prevent the sap from circulating. In course of time injurious insects, such as borers of various kinds, find their way through crevices, and parasites gradually destroy the trees. Trees which are thus especially tender are, among cultivated trees, Apples and Pears, and among wild trees, Weeping Willows, Poplars, young Oaks, Maples, etc. A tree when once injured seldom recovers if left to itself, but dies, or at least becomes sickly. In order to counteract this fatal force of excessive light and heat combined, the horticulturist encourages lower limbs and foliage, prunes his trees low, or otherwise shades the exposed parts. Nature works very much in the same way. Young trees growing in heated regions are covered with lower limbs thickly set with foliage, or develop large weeping tops or crowns with drooping branches, which shelter the tender stems as effectually as if they were covered with an umbrella. That such a shade is absolutely necessary can be clearly demonstrated. There is, for instance, no more tender tree than our common Weeping Willow, a native of the hot region of Asia Minor. This tree flourishes even in our warmest regions under proper conditions of moisture, as long as its natural form is not interfered with. But let any one prune back its limbs and cause the direct rays of the hot sun to strike its trunk, and the tree will soon become diseased and die. The dying of Weeping Willows is common all over the warmer parts of this state, and is everywhere to be principally ascribed to the cutting away of limbs and to the entrance of heat and direct light.

"The excessive heat and light have also a bad effect upon the ground in places where rain or other moisture is scarce. The sun dries out the soil and makes it too dry for the trees and plants. To counteract this heat, nature causes lower limbs to spread out as close to the ground as possible, or furnishes the tree with large, dense and rounded crowns, which cover the soil with shade and prevent the moisture in the immediate vicinity of the trunk and roots from drying out.

"Nature furnishes also other remedies, such as peculiar position of the leaves, tough and hardy bark, gray and light colors of leaves and stems, hairs or cells especially constructed to withstand evaporation or heat.

"While the snow especially affects evergreens, the heat and light affect evergreens and deciduous trees almost alike.

"In the tropics the intense heat develops another tree form, the umbrella form. In this region the heat is always accom-

panied by moisture, and is thus never excessive or dangerous for trees which naturally seek the light. The moisture and heat combined produce a most vigorous and dense vegetation, the very opposite to what is found in the arid zones. The effort of the tree is therefore concentrated in its endeavor to reach the light and to push out from the dense shade nearer the ground. The most vigorous growing trees in this region send up straight and undivided trunks to a level with the top of the dense undergrowth, branch at this level and form immense umbrella-like crowns above less vigorous trees. This umbrella form gives to the tropical landscape a distinct and characteristic appearance. A tendency to assume such an umbrella form can also be recognized among those trees of the temperate zone which grow in moist places, such as river-bottoms, cañons and other sheltered localities—trees, in fact, which delight in moisture. But nowhere is the form so pronounced as in the tropics, where it is common with all large species of the denser forests. The uplands of the tropics, where the rainfall is less and where heat and drying winds are more powerful, and where, accordingly, the vegetation is less dense, the umbrella form is rare, or where it exists is caused by other agencies.

"The origin of the tropical umbrella form is, therefore, not exactly identical with that of the umbrella form assumed by most Pines in such districts as the Mediterranean or the Gulf region of the United States, and, to a certain extent, also by a few more northern Pines. This umbrella form is caused by the falling off of the lower branches, which never possess the strength of the upper limbs. The umbrella form, however, greatly favors their struggle against wind and heat.

"In these drier places in the tropical districts the umbrella form gives place to the globular form, the conditions there being quite similar to what they are in the drier regions farther north. Observe, for instance, the form of the Ceiba (*Bombax Ceiba*), which inhabits drier localities in the Central American tropics. This tree is almost globular in shape, in order that its branches may give necessary shelter to the trunk and to keep away the reflected heat. An effort to change the form of this tree by pruning results fatally, as the branches become sun-scalded and a prey to borers, which eventually destroy the tree. In crossing Central America I was especially impressed by these different tree forms, characteristic of different regions. Along the lowlands of the Pacific coast, up to 2,000 to 3,000 feet, the characteristic form of the various strong-growing trees was the umbrella form. Above 3,000, and from that altitude toward the interior in the dry and warm district, the globular form predominates. As we ascend the interior highlands in the vicinity of Coban the climate suddenly changes and becomes very moist. With this change comes also a change in the form of the trees, which here assume the regular umbrella form. The same climate continues uninterrupted to the Atlantic coast, and the district is characterized throughout by the predominating umbrella form.

"All trees require more protection when young, and this explains why young trees are shaped differently from older trees. Thus the form of a young specimen of the common Blue Gum (*Eucalyptus*) is well known. While young the tree is pyramidal, and the sloping branches are covered by horizontally extended leaves. No form can be more adapted to withstand heavy winds. As the tree grows older, the stem stronger, and the roots penetrate deeper, this original form is not required any more, and the tree assumes a semi-umbrella-like crown.

"If we consider the principal forms of trees in their connection with influences of wind, snow, rain, sunshine and heat, we find that the various forms may be grouped principally under the following heads:

"(1) The upright form, with a central undivided trunk and with downward sloping branches. This form is possessed by most conifers inhabiting snow-visited regions. The downward slope of the branches facilitates the shedding of the snow, while the undivided trunk offers less resistance to heavy loads of snow. Forked or branched trunks would split or break.

"This form may be either necessary to the species, as when the latter is confined to snow-visited districts (example, *Picea amabilis*), or it may be inherited and continue as a characteristic of the species which grows in a warmer climate, but which evidently had been evolved from a species which once inhabited colder regions. Example: the Redwood (*Sequoia sempervirens*), Lawson Cypress (*Cupressus Lawsoniana*) and many other evergreen trees inhabiting the moist, snowless climate of the Pacific coast north of San Francisco.

"(2) The upright form, with erect or horizontal branches. The upright trunk in this form must be considered as inherited from ancestors where it was a necessity. Later on the sloping

branches gradually assumed a horizontal position. Example: most species of Cypress, Yew, Juniper, etc., of a more southern origin. It is interesting to note the form of *Cedrus Deodara*, or Himalaya Cedar. This tree, growing in regions of Himalaya where heavy snowfalls are not infrequent, possesses while young characteristically downward sloping branches. *C. Libani*, Lebanon Cedar, which is only a form of *C. Deodara*, possesses no such sloping branches, but horizontal branches, evidently developed in a climate where the absence of heavy snow has made the downward slope of the branches unnecessary. Most species of Juniper possess erect branches, as would be expected in a genus which finds its most congenial home and greatest development in the warmer regions of the Mediterranean, where snow is almost unknown.

"One species (*Juniperus communis*), however, which is common in northern Europe, is distinguished by a very different form from the southern species, being dwarfed, prostrate, and repeatedly branched. But that this form of the European Juniper is not the natural one, can be seen by the fact that whenever this species is transferred to snowless localities it at once assumes the upright form, growing as straight and slender as a southern Cypress. Similarly we find this upright form possessed by all specimens of this Juniper which grow in close proximity to smelting works, where the heat is strong enough to melt the snow. The different appearance of this Juniper in such localities is really most startling.

"Pines which inhabit snow-visited regions are, as a rule, very upright, with downward sloping branches, while the southern Pines, both in Europe and North America, as well as in Central America and Mexico, have branches which either spread horizontally or which stand erect. Compare, for instance, *P. Lambertiana* and *P. Cembra*, which inhabit snow-visited regions, with such species as Aleppo Pine (*P. Halapensis*), *P. maritima*, *P. insignis* and *P. Sabiniana*. Judging by the forms of most species of Pines, it would seem as if this genus is more of a southern origin than, for instance, the various genera of Firs and Spruces which, through their very characteristic undivided stems and sloping branches, indicate their origin in the snowy regions in the north.

"(3) The globular form. This form is possessed by trees in warm and dry regions or localities. The object of the form is to protect the tree from sun and heat and to preserve the moisture in the soil around the root. Example: the Live Oak, the wild California Walnut, the Texas Umbrella and the tropical Ceiba, or *Bombax-tree*. The Mesquite of the Mojave Desert belongs to this form.

"(4) The umbrella form. This form is principally found in moist tropical climates. The object of the form is to give to the tree as much sun and heat as possible, which can again only be had at a certain altitude above the tops of the dwarfing vegetation. Example: various papilionaceous trees, as well as most varieties of trees in the tropical lowlands of both continents.

"In connection with this, I will call attention to the form of the bases of the trunks and of the surface-roots in trees growing in moist places, especially in the tropics. The trunks branch out above the soil and form peculiar horizontally compressed roots, sometimes five to six feet high, but only a few inches thick. Such surface-roots are found in most tropical trees, as well as in many swamp trees; for instance, the Swamp Cedar of the Mississippi delta. The object is to steady the tree when floods or excessive rains soften the ground; round roots would then offer much less resistance."

Notes.

Excellent peaches from Georgia are now offered on all the fruit-stands of this city.

Dr. Ignatius Urban has just issued in separate form his *Addimenta ad Cognitionem Floræ Indiæ Occidentalis* from the fifteenth volume of Engler's *Botanischer Jahresbericht*. It contains descriptions of new Antillian species, with critical notes on others, based principally on recent exploration in the West Indies.

What promises to be a work of much value to the many horticulturists in America who read German is the recently announced *Forsliche Botanik* (Forest Botany), of Dr. Franz Schwarz. It will be published by Paul Parey in Berlin, will form a large octavo volume illustrated by two plates in photogravure and 456 wood-cuts, and will be sold for 15 marks.

On the roof of the New York State Building, in the World's Fair-grounds at Chicago, which is to be built by Messrs. McKim, Mead & White, three terraced gardens will be ar-

ranged. Doubts have been expressed whether, owing to the heavy, smoke-laden air of Chicago, the recent movement to popularize roof-gardens in the city itself will be successful. But during a single summer, when neither pains nor cost will be spared to maintain them, those on the New York State Building will probably be made very beautiful features.

Mr. H. E. Van Deman, of the United States Department of Agriculture, writes to *Orchard and Garden* that in Norfolk the Hoffman Strawberry has been selected as one best suited for market purposes. Its points of excellence are the earliness, firmness and good color of the fruit, the vigor of the plant, and the stiffness of the peduncle, which holds the fruit well up. The defects of the berry are poor quality as a desert fruit and moderate productiveness. Early, clean and firm berries which will endure shipment to distant markets are the great points which the market-growers desire.

Some thirty students attended the spring course of lectures on New England trees and shrubs, recently concluded at the Arnold Arboretum. More than half of them were school-teachers from Boston and its neighborhood, while the remainder were mostly persons who are in charge of parks or large private grounds. The lectures were specially adapted for the instruction of persons who have no botanical knowledge, and dwelt upon the useful and ornamental properties of the plants in question, their habits of growth, characteristic diseases and other peculiarities. An autumn course of fifteen similar lectures will begin on September 7th.

A monument is to be erected in Paris to the late Monsieur Alphand, the famous landscape-gardener and director of public works. The committee in charge of the matter, which includes Puvis de Chavannes, Charles Jacques and other artists, as well as officers of the Government, appointed one of its members, Charles Garnier, the architect of the Opera House, to designate the most suitable site. He pronounced in favor of some point on the avenue which leads to the Bois de Boulogne, and this suggestion has been adopted by the committee. The monument will be architectural in character, and its preparation has been confided to Monsieur Formigé.

"Rosemary," says a German writer, "in southern Europe is plaited in a bride's hair. It is also used to sprinkle holy water on the coffin in which, with other flowers, it is used for decoration, and it is carried in the bouquets of the mourners. It is commonly planted on graves. Yet, hung on the entrance to the house or porch, it brings good luck to the household, and protects against thieves. Moreover, it possesses the power of renewing youth. There is a tradition that a very old, queer, shriveled queen was helped by means of a recipe which she was careful to bequeath to her heirs. It prescribed: Six pounds of Rosemary, crushed in a mortar, mixed with water which was to be bathed in thrice a day."

In a recent number of the *London Academy*, Mr. H. A. Evans called attention to the fact that when Shakespeare twice mentions the potato (in *Merry Wives of Windsor*, V. 5, 21, and in *Troilus and Cressida*, V. 2, 56), it is the sweet-potato, not the white potato, that is meant. The contrary fact has usually been assumed by commentators, and by dictionaries which include the quotations to which we refer. But *The Century Dictionary* is more accurate. It says that the first meaning of potato as an English word was sweet-potato, and that it should thus be understood whenever it occurs in works written before the middle of the seventeenth century. This meaning, it adds, is now obsolete in England; and the sweet-potato itself is scarcely known except by name to our transatlantic cousins.

A month ago the Earl of Roseberry formally opened Brockwell Park, and South London is now provided with one of the very prettiest of all the parks of the great city. It is not so extensive as some of the others, since it covers only seventy-eight acres, but the ground presents an unusual variety for its extent. It is finely timbered, undulating in surface, and much of it is thoroughly picturesque, showing bits of scenery which artists delight to paint just as they find them. Altogether, it has an appearance of rural remoteness, and it is the purpose of the superintendent to develop the natural beauty that is already there rather than to attempt any grand scheme of creation. It will contain, however, an old-style walled-in garden, laid out in geometrical Dutch style. This is not new, but already exists with its old fruit-trees and crumbling walls and general air of seclusion, so that it was wise to preserve it and continue it as a genuine old-fashioned garden, which will offer a piquant contrast to the natural grounds about it.

The latest issue from the botanical department of the University of Nebraska, being the third of the new series of its contributions, consists of a second edition of Webber's *Appendix to the Catalogue of the Flora of Nebraska*, with a supplementary list of recently reported species by Professor Charles E. Bessey. Mr. Webber's Catalogue was originally published in the sixth volume of the *Transactions of the Academy of Science in St. Louis*, bearing the date of March 12th, 1892. Professor Bessey's supplementary list contains one hundred and seventy species discovered since Mr. Webber's paper went to press. It contains mainly the plants collected by Mr. Rydberg in the western counties, with others made by members of the University botanical department, and by Dr. Hapeman, of Minded, and the Rev. J. M. Bates, of Ballyntine. A periodical publication of all additions to the flora of the state will stimulate, Professor Bessey suggests, botanical students to a closer study of its flora, and encourage them to deposit specimens of newly discovered species in the University Herbarium. Correspondence is solicited by the department of botany to further this end.

Mr. Albert Koebele, who is in Australia collecting beneficial insects, has sent to the State Board of Horticulture of California a new Lady-bird that preys on the Cottony Cushion Scale. It was through the instrumentality of Mr. Koebele that the *Vedalia cardinalis* was introduced into California and accomplished a work which was without precedent in the annals of economic entomology. This new Lady-bird is called *Novius Koebelei* and slightly smaller than *Vedalia*, the mature beetle averaging about one-eighth of an inch in length. Only three specimens were received, and these were placed in a small jar infested with the scale. One of the insects died, but two of them changed to the chrysalis state, and in a few days perfect beetles emerged, which were, fortunately, male and female. Three days later the female deposited eggs, which hatched in five days. The young larvæ were carefully reared, and, after passing through three molts, changed into the pupa state, and fifty-five perfect beetles were secured in just thirty-one days from the egg. When liberated on trees they will, no doubt, pass through their transformation in much less time, so that there will be thousands of beetles for distribution very soon. It is to be hoped that they will be as efficient as the Lady-birds of Mr. Koebele's original importation.

The great mass of flowering shrubs have passed their blooming season by the end of June, but those who enjoyed a visit last week to the grounds of Mr. Charles A. Dana, at Dosoris, Long Island, observed four shrubs in particular which were flowering finely, and all of them natives. The first of these was the White Swamp Honeysuckle, *Rhododendron (Azalea) viscosum*, which was still bearing its showy clusters of flowers, some of them pure white, others ranging to pink or pale rose color. Near a group of these *Azaleas* was a specimen of *Stuartia pentagyna*, an American representative of the Tea family, which is a native of the mountains of North Carolina and Georgia. It is pretty generally hardy in this latitude, and although it is one of the most attractive of summer-blooming shrubs and has been cultivated for more than a century, it is still so rare in gardens that it has no common name. The flowers are three or four inches across with cream-white petals, and resemble some of the single *Camelias*. The Oak-leaved *Hydrangea* is another shrub from the same region which was figured as long ago as Bartram's time, and yet is comparatively rare. On the banks of streams in its native home it sometimes attains a habit almost tree-like and a height of some fifteen feet. The specimens on Mr. Dana's grounds were not so large, but the long thyrsoid panicles of white flowers are very showy. The panicked *Hydrangea (H. paniculata)* resembles this in its inflorescence, but its flowers were not yet fully expanded. This, too, is a beautiful shrub, and although it was sent out long by the Messrs. Parsons & Sons, of Flushing, it is rarely seen. Its variety *Grandiflora*, which, to our taste, is not so attractive, has become very common in gardens. The Michigan, or Prairie, Rose (*Rosa setigera*), and the only American Rose with climbing stems, was here trained to a pillar, and made a beautiful picture. It was covered with corymbs of large single flowers, some of them nearly three inches across, of a deep rose color on their first appearance, but turning nearly white before they fade. These immense clusters in the greatest profusion, backed by the broad handsome foliage of this plant, make it very desirable, and when grown in good soil and fed generously it is more beautiful than any of the double-flowered climbing Roses, such as the Queen of the Prairies and the Baltimore Belle, which have been derived from it as a parent.

The Love of Nature.

ONE of the noticeable characteristics of this century is a growing love of natural scenery, but it may be questioned whether the love of nature is also growing, for a distinction must be made between the two. The first is a simple emotion—an instinct rather than a faculty—and, like all primitive instincts, it lies at the very foundation of being, having its roots somewhere in that mysterious region below consciousness. Perhaps it is stronger among the savage than it is among the civilized races of the world, but it is yet the birthright of every healthy child.

The appreciation of natural scenery, on the other hand, is a complex emotion which involves thought, memory and imagination, and as it rarely manifests itself in childhood it probably did not exist in the childhood of the race. Wherever this appreciation is found, whether among modern nations, among the Hebrews as indicated in their literature, or among the Greeks and Romans, as is evident from the skillful way in which their architectural creations were placed with reference to their natural surroundings, it is the outcome of an advanced, perhaps of a decaying, civilization. The towering mountain stirs the imagination of the boy, but it is to deeds of exploration and adventure. The dense forest lures him, but its chief attraction is the game it covers. The brook which sparkles through the meadows delights him, because it turns his water-wheel or excites his hope as an angler. And yet, blind as he may seem to the grandeur of the one or the beauty of the others, mountain, grove and stream, each plays its part in molding the boy's taste and character, and in after years he will be drawn to them by a deeper love, because they are inseparably blended with the careless happiness of childhood and youth. It is through some experience like this that the race has passed. Earth first ministers to man's necessities; in so doing it develops his faculties and awakens new powers, until at last, when he has gained dominion

over it, the ability to discern its beauty comes with the leisure to enjoy it.

The pleasure which springs from the contemplation of a beautiful landscape differs in kind with each spectator. It may have no deeper source than the mere love of beauty, and it is then refreshing to the jaded spirit simply because the beauty is pure and appeals to no sordid or material interest. But when to the beauty of a landscape is added the charm of romantic and historic association, the pleasure it awakens is lifted above the region of the purely sensuous into the realm of sentiment and imagination. To the man of religious spirit, to whom the visible universe is but the thought of God made manifest, the mountain gloom and the mountain glory speak first of the majesty and dominion of the Most High; while the smiling landscape, with its suggestion of happy homes and sheltered lives, brings tender thoughts of Him who notes even the sparrow's fall. Among the same scenes the man of science, if he has not sacrificed all the poetry in his nature in the search after material truth, will be lost in wonder that the tumultuous and conflicting forces which have lifted the mountains from the depths of the sea and crowned them with everlasting frost can yet in obedience to the same immutable laws subdue their might to offices of tender grace, can stoop to paint the lily and add perfume to the violet. And so to each the landscape has its mission; to the dilettante it brings a fresh sensation; to the man of feeling a noble emotion; to the man of religion, thoughts of devotion and gratitude; to the man of science, reverent wonder at the mystery and majesty of natural law.

The love of nature, at first an instinct, springs from a deeper source than the admiration of scenery, and it may, when disciplined and chastened, awaken a still more profound delight. The heaven which lies about us in our infancy may be at first only a dim consciousness of the universal life of nature, that life which throbs in every tree and shrub, the instinct in every clod "which comes to a soul in grass and flowers." It may be an inheritance from some far-off age, when man was nearer nature's heart than now, some memory of which haunts the mind of the growing boy and brings much of the unconscious joy of childhood. Most of us know too well how this "vision splendid" fades into the light of common day, but when in some fortunate individual it is retained through manhood, is assimilated by the intellect and shaped by the imagination, it becomes "the vision and the faculty divine," the rare gift of the poets of the race. Every one who retains it as a conscious possession is at heart a poet though he may lack the poet's gift of expression. The lover of natural scenery is wont to talk with eloquence of the pleasure he finds in the contemplation of landscape beauty, but the true lover of nature says little of his joy. He cannot measure or describe it, but when alone in the dense forest or in some sunny glade a mysterious sense of kinship with the silent forces working all about him, or a dim consciousness of a haunting presence, comes to him unbidden and ravishes his soul with suggestions of a more awful beauty some day to be revealed, and after such hours of communion with nature he can return to the noisy world refreshed in spirit and strengthened for the inevitable conflicts of life. It is only the chosen few whose early affection for nature has become a controlling passion who enjoy in full measure this vivifying power.

Since the love of natural scenery may be cultivated, why may not the child's love of nature be preserved? Like other fine instincts, it requires delicate handling. It too often vanishes early, crushed out by hard necessity or crowded out by the insincerities of an artificial life. Nature does her utmost to retain her hold upon the child, the flickering sunbeams tempt him, and every moving shadow has a charm even in his mother's arms. The flowers of the field are his chosen playfellows as he grows; trees whisper to him their secrets; all the myriad sights and sounds of earth and air woo him with their promises of happiness, and while the enchantment lasts the little traveler needs no

other guide through the labyrinth of beauty about him than his eager curiosity. But as this begins to wane would it not be wise to direct his attention a little deeper to the infinite variety of leaf and flower, the endless diversity of form and structure in bird and insect, shell and crystal? As his mind expands why not take him into Nature's workshop to note some of the slow and mysterious processes of growth, the circling of the sap, the perfection of the flower and fruit? Surely some dim wonder at the miracle which binds all the forces of the universe to each tiny germ in fulfilling its destiny, will fill his awakening soul with as deep a delight as that which in his earlier years greeted his keen and eager senses. In this way the study of natural science could begin without its drudgery; the child's powers of observation would increase with their exercise, and the closer investigation of nature about him would keep his interest as fresh as it was when he first began to look and listen. And so as his faculties one after the other are enlisted in the delightful work, he "hearing gains who had but ears, and sight who had but eyes." Is it too much to say that if the original love of nature, which is every child's inheritance, was thus fostered and cultivated, that he would never lose that instinctive delight in the natural world, but that this delight would be slowly transmuted into the possibilities of a deeper and richer joy as maturity was reached?

To speak of gardening as an occupation for children in connection with a subject of such profound philosophy would seem at first to detract from its dignity, but nature has been before us and has implanted in the child the impulse to dig, which awakens almost as early as the desire to catch the sunbeam, and which is quite as vital, perhaps, to its perfect development. It is the law of our growth, that the finer gifts or graces can only be gained on the condition that their acquirement is not the object sought. Thus the child who is set to work in a garden of his own as soon as he has the moderate amount of strength and skill to begin the work, will glean a much richer harvest than the flowers or fruit which will be one reward of his toil. We most love that for which we have made some sacrifice, and, therefore, the growing things upon which the child has spent his tiny strength will be far dearer to him than the finest blooms of his father's greenhouse, while his interest in their relatives of the field and forest will be retained and strengthened by many associations.

This diversion in the garden, therefore, will help to keep fresh and strong the original love of nature which is the child's inheritance, so that he will be more likely to carry it with him into the strenuous work of manhood. So much has been said already in these pages of the influence of gardening upon character, that there is no need of enlarging upon this branch of the subject, but it may be worth while to invite attention to one among the benefits to be derived from early familiarity with the garden and its cultivation, which is rarely, if ever, taken into account. The child will love his garden and be happy in it. When early manhood comes, and during the busier years when he must test his strength in the world of men, his garden, like other pleasures and interests of boyhood, will take a subordinate place, but in the evening of his days, after the stress of his life's work is over, there will inevitably return the longing to possess and transfigure some portion of the earth's surface. This desire comes naturally to almost every man. The idea of rest in declining years seems to be inseparably connected with rural scenes. The paradise to be regained is never within the walls of cities. This is true even of the city-born and city-bred, and it is doubly true of one reared in the country, and when such a one takes up with renewed interest the occupations of his boyhood he finds, to his surprise, that in addition to the flowers or fruit which reward his care there is an ideal harvest of associations which may make his closing years rich with a beauty and a pathos all their own. Every leaf and flower touches some mystic chord of memory and association, and as he rests under the shelter of his Vine and Fig-

tree the glory of that far-off time gilds his downward pathway with a tender radiance and revives the spirit of that early day when,

—meadow, grove and stream,
The earth and every common sight,
To him did seem appareled in celestial light.

It appears from the seventeenth annual report of the Board of Park Commissioners of the city of Boston, which has just appeared, that, up to the present time, eight millions of dollars have been expended on the park system—about three millions and a half having been devoted to the purchase of land, four million three hundred thousand dollars to construction, and rather less than two hundred and fifty thousand dollars on maintenance. Considerable progress has been made during the past year in completing the system, although none of the parks are yet finished, with the exception of the Charles Bank, a small marine esplanade on Charles Street, in the city proper. None of the great parkway, which ultimately will stretch from the end of Commonwealth Avenue, passing through the Back Bay Fens, embracing Jamaica Pond, skirting the Arnold Arboretum and Franklin Park, and finally reach the marine park in South Boston, is yet open to the public. This, however, will be the great feature of the system, and will furnish a continuous and interesting drive of about fifteen miles. Boston, in spite of the liberal expenditures which the city has made in the last seventeen years, is still very poorly provided with parks. Franklin Park, of five hundred acres in extent, is the only park in the whole system in the true meaning of the word, and the only one where large masses of people will be able to find rural enjoyment and repose. Serious efforts are now being made to increase the park area in eastern Massachusetts, and it is not improbable that large bodies of unimproved forest-land, like the Middlesex Fells north of the city, and the Blue Hill range south of the city, may be added to the park system of greater Boston, which, if the growth of the last few years is maintained, seems destined to become one of the great centres of human habitation.

The Gardens at Wellesley, Massachusetts.

AMONG the pleasant excursions to be made in the suburbs of Boston one of the easiest and most agreeable is the trip to Wellesley, where there are many things to see that are of interest to the lover of trees and gardens. The grounds of the college are attractive from their fine natural capabilities, of which the best is unfortunately not being made, and I hope that before long the advice of some expert will be taken with regard to the class-planting of trees, or great confusion will result. It strikes me that if, for the present, each class should celebrate its anniversary by cutting down instead of planting a tree, it would perhaps be of more advantage to the picturesque development of the property.

The situation of the college grounds is delightful. The surface is irregular and well wooded, and there is a beautiful lake to form an attractive feature from whatever point it is observed, but the opportunities for vistas are greatly neglected, and the elevation on which the college stands is dotted all over with meaningless groups of trees, which detract from the dignity of the really imposing site. There is no outlook upon the lake from the balcony of the main building, as tall trees wholly intercept the view. If some of these are necessary for shade, it seems as if it still might be possible to arrange openings through which the lovely sheet of water might be seen, and thus enhance the beauty of the outlook from the handsome hall, which would then command a delightful scene from which it is now at midsummer wholly cut off.

Another thing which struck me as particularly reprehensible, was an ugly straight row of Copper Beeches, planted between the avenue and the woods. This avenue was planted with taste by the original proprietor, Mr. Durant, with Elms, which have attained a good size and now shade it agreeably. Between this row of Elms and the dense woods on the right a fine smooth stretch of grassland had been appropriately left, which produced an excellent effect, but the row of small purple Beeches, apparently of recent introduction, into the very middle of this pleasant level green, is a great mistake and

disfigurement. In the first place, Copper Beeches are trees to be used singly and with the utmost caution. At best, they are a discord in a green landscape, which can only be made endurable by a proper resolution into harmony, and even then the best authorities think we should do better without them, as they represent a doubtful note. One tree of this complexion edging a deep green wood is sometimes pleasing as well as curious, but a stiff row of them, parallel with a row of Elms, is as undesirable a feature as could well be introduced into a landscape-garden.

Some of the memorable trees of Wellesley seem also to be set out in the most unfortunate positions. I was shown a tree planted by Queen Emma, of the Sandwich Islands, which is so near a wood that in two or three years it will be completely overshadowed by the branches of the larger trees, and the class-tree of this year is also put where it will never have a chance to develop properly. It seems to me that the college authorities should take the advice of some competent landscape-gardener as to what needs to be done to preserve the beauty of these grounds. A cultivated and well-trained eye should decide where class-trees can be planted with impunity, and dictate what sorts of trees should be employed for the purpose, and how much space should be left between them, if they are to grow into handsome single specimens, and also where groups can be placed with advantage so as not to interfere with the general effect.

The opportunities here are very great, but it is not desirable to transform these park-like grounds into a meaningless mass of ill-assorted trees, which do not compose well with each other or create a pleasing picture. I recognize all the charm of these academic shades, and realize how dear this lovely spot must be to the hearts of its "sweet girl graduates," but all the more, it seems to me, that its future should not be left to irresponsible planters, but that careful provision should be made to preserve and enhance its beauty. As years roll on some of the older trees will die; these should be succeeded by others. A careful system of forestry should prevail, by which the best of the closely planted trees should be protected, and provision made for proper successors to those which must in time be removed.

Above all, more open space should be preserved, as a wide grassy stretch, with a view of the lake, serves to bring out the groups of trees with good effect, and to increase their value in the composition. A careful study of Mr. H. H. Hunnewell's place, on the opposite side of this sheet of water, shows the worth of knowledge of effect and a settled plan in planting. There the lake is utilized to increase the beauty of the scene, with enchanting results.

From the house there are unobstructed views of its silvery surface, the trees being kept when they do not interfere with a satisfying sight of its broad expanse, which combines delightfully with the smooth lawns, the quaint terraces, or the rustic wildness of certain portions of the beautiful grounds. Relieved against it the stately natural evergreens gain a richer majesty, and it combines with the formal surfaces of the clipped Hemlocks and Beeches and Pines in the topiary garden, in a way that recalls memories of ancient villas of renown upon the lakes of Italy, while, contrasted with its blue, the white pillars of the balustrades seem of Attic value.

Those whom its generous proprietor so freely permits to see these gardens may well be grateful for a chance to know in our own land some of the charm that haunts the classic grounds of the old pleasure-grounds of the Colonna and the Serbelloni. Whether such a sight comports with a New England garden is of little moment. Are not our skies as blue, our hills as softly swelling, our summer suns as hot, as those of Italy? Why not, then, capture this Old World charm, this strange fascination that lingers in a sight of the subduing of nature to art, that suggests the pride of princes who would rule all.

I have sat for hours in the deserted gardens of Rome, where once the haughty old Colonnas trod, and sought to find the secret of the way they move one. Why do these straight terraces of clipped Yew, these formal masses of Ilex and Cypress and Holly, these headless statues, and moss-grown fountains, with their trickling streams and vine-wreathed lions, hold so dear a charm that when one comes in New England upon their semblance he must needs be thankful for this reminder of a never-to-be-forgotten past?

I doubt if it is only the mere strangeness of this formal gardening which so appeals to the untraveled multitude that they regard it with interest and wonder; there is something deeper than that, which, I take it, is the mastery of man over nature, his all-compelling hand that forces the stubborn Pines to do his bidding, the wayward Hemlock to bend to his eccentric

will. It is the humanity in it which attracts—which thrills us with an odd satisfaction. This violation of law, this enslavement of wild beauty has a relish for our perverted souls, for is it not our fellow-man who has accomplished this audacity, joined issue with the Creator, defied the eternal forces? Sensation is a complex joy; it cannot always be resolved into its elements, and it is hard to say why, on the shore of a Massachusetts pond, a series of terraces planted with extraordinary pyramids and umbrellas, and broad hedges and columns of foliage, should be as interesting and delightful as they are upon the Lakes of Como and Maggiore, where they are the survival of the fashion of a by-gone day.

Stone staircases lead one down from one level to another; at the base a carriage-drive is separated from the water by one of those white balustrades so familiar in Italy, upon which a peacock ought always to be sitting and pluming his exquisite feathers. Across the water the red walls of the college buildings are picturesquely gleaming through the trees, with little boats moored upon the shore and their feet. Along the edge of the lake winds the carriage-drive, separated from it by a fringe of trees. Strolling on foot along the terraces, even as one does at Isola Bella, of a sudden you find yourself in a rustic garden, stony and wild, where small flowers bloom and Ferns run over the rocks; a winding path leads down a declivity to a pavilion on the edge of the water, where you can sit and look back upon the Italian garden with its strange forms of Pines, clipped to imitate a series of toadstools or umbrellas one above the other, of Junipers personating a pyramid, of Cedars masquerading as gate-posts with round balls atop, of rosy Beeches in square masses as unlike a tree as possible, of a great wall of feathery Hemlocks with a steeple of green at regular intervals along it. For forty years this quaint garden has been planted and maintained for the delight of three generations, and still affords, perhaps, the only specimen of an Italian garden in this country.

The whole of this fine estate of six hundred acres gains interest from the fact that its present proprietor has made it what it is, since 1852, from an uninteresting, flat, sandy arid plain, with nothing upon it originally worth retaining except one large Oak-tree, which has now attained magnificent size. The skill, the patience, the unending labor necessary to evolve all this beauty from such unpromising material, are forever worthy of admiration. Years ago we read the account of the foundation of these gardens in Mr. Henry Winthrop Sargent's supplement to the sixth edition of Mr. Downing's book on landscape-gardening, and were greatly heartened and cheered thereby in our own feeble efforts.

It is hard to realize that even forty years can do so much for a desert, but when, seven years after its beginning, Mr. Sargent wrote his account of it, the place was already noteworthy and interesting. Therefore, who may not take courage to persevere in humble efforts to beautify some barren spot that it may be his fortune to possess? Energy, industry and delight in the work will accomplish wonders, and if any feel discouraged let them come here and look about upon these lofty evergreens in the Pinetum, raised from seed, these stately Oaks and Magnolias and Maples that have grown beneath their planter's eye to their present proud proportions, and then sow his seed, and set out his tree with undaunted faith that he shall live to reap the fruit of his labors and sit beneath the shadow of his plantation while he is yet hale and vigorous.

Not all of us can give to our nurslings the assiduous care and generous treatment that Mr. Hunnewell accords to his, but we may well bestow upon one tree the attention that he has awarded to thousands, and from that one win a proportional satisfaction. Enjoyment, luckily, can be elicited from one acre as well as from a thousand; possibly a concentration of interest upon a limited field may bring in an increased return of satisfaction. So far as my experience goes, the small planter has the same joys and sorrows as the large one; it is merely a difference of scale. In his one Water-lily in a mud-hole, the former may have the same emotions as the latter in a Victoria regia brought to blossom in an elaborate tank with infinite care and pains. The reward, after all, is success in the undertaking, be it great or small. This lesson learned, happiness is within our grasp. Seek the attainable, and no man need be unhappy. If you have room for one Oak, plant your acorn and watch its growth—it is the epitome of a park. Plant your little wood-lot with Pines or Nuts, and cherish the seedlings, you master the lesson of the forest. Work with shrubs if you have no room for trees, with flowers if the space be too limited for shrubs, and from the results achieved will come delight in mastering difficulties, new knowledge, fresh desires, a hearty homely interest in the world about you, a link of sympathy with every son of Adam, who, from the lucky fall of that

idle sinner, has gained a chance to earn his bread by the sweat of his brow.

Hingham, Mass.

M. C. Robbins.

The Old-time Southern Garden.

ONE of the most characteristic features of the old-time southern home of the better class was the garden. The slovenliness of the farm stopped short at the garden-wall, within which all was care and order. Rows were as straight as rays of light, and walks and borders were neatly kept. This was woman's domain, and the women of the south were careful even to scrupulousness.

No seeds were bought. Such a purchase would have been held an unpardonable extravagance. The few northern seeds sold at the south were used in the town gardens. Every gardener saved her own seed, which, after being carefully selected and dried, were hung well up out of the reach of meddling bodies. If any housewife gained a reputation for the excellence of any special vegetable she was pretty sure to be called on to supply half the neighborhood gratis. Among the small slaveholders the manual labor of the garden usually fell on the female house-servants. On the larger farms there was usually a regular gardener. One of the older men, who had been retired from the heavier work of the fields, was usually assigned to the garden, as one was also set to run the mill. If so, he was sure to carry all the superstition of his race into his new calling. The moon was omnipotent in the southern garden. Everything, from the planting of a seed to the cutting of a bean-pole, was regulated by that exacting luminary.

As the system of farming consisted in clearing fresh land as fast as the old was worn out, many farmers used little or no stable-manure in the fields, allowing all of it to go into the garden. Fertilizers were unknown, but droppings from the hen-house answered very well for forcing. The result of this was to make the garden a real oasis amid its too often barren surroundings. The variety of vegetables was not great, but the quality was of the very best. Indeed, even after discounting the enchantment of boyhood, there still seems to have been an excellence in a few of those old-time vegetables which the latter-day varieties have hardly attained, and certainly not surpassed. The originator of new varieties has been more intent on looks than on real merit. This is certainly true of strawberries. I have tried in vain to obtain varieties as fine for the table as those that grew in the old garden away back in the fifties. In every remove from the wild strawberry something seems to be lost in flavor, which no doubt arises from the desire of the propagators to meet the popular demand for large and showy fruit.

Tomatoes had come to be generally grown, though not relished by all to the present extent. Egg-plants I never saw, nor Okra till the seed was needed as a substitute for coffee during the war. Parched and ground, they formed the most popular beverage of those scant times.

In the ante bellum garden the Asparagus-bed, which was an almost sacred spot, responded liberally to the great attention it received. An early cabbage was grown, surpassing in size our present early sorts. Beets were excellent. Only one kind of snap beans was raised, a small green one; and one kind of butter beans, also a small variety. Few persons relished Parsnips or Carrots, though a few were generally grown. Salsify, or vegetable oysters, as it was then always called, was grown and eaten to a much greater extent than it is now.

A flat cymbling, or summer squash, produced on a luxuriant vine, which grew so fast that it was accused jocosely of chasing the frogs out of the garden, was the kind in general use. Pumpkins grown in the low-ground corn-fields were fed almost exclusively to stock. I never saw any cooked, or tasted pumpkin-pie until after the war.

Cucumbers and onions were grown in large quantities and greatly relished by all, being eaten together in vinegar. Vast quantities of cucumber pickles were also consumed. Almost every garden, too, had its Artichoke corner, originally planted by some long-forgotten hand, and now yearly producing enough for pickles without replanting. Irish potatoes were grown in abundance, usually in a "lazy bed," so named from the fact that after planting no further work was required. This bed was a plot in which its potatoes were put about a foot apart each way, lightly covered with earth, and the whole was then covered with leaves and litter to the depth of a foot or more. The yield was enormous, the tubers growing often above ground where the litter gave them full room to expand to the utmost.

Many "lazy beds" afforded potatoes from May till far on into the following winter, the tubers being left in the bed and

taken out as needed. This plan might still be followed with profit to the gardener, especially at the south, where it is difficult to induce late-planted potatoes to grow, or to keep the early ones through the summer and autumn, as they soon shrivel and get bitter. As northern-grown potatoes for seed cost us from \$1.25 to \$1.50 a bushel, many dollars might thus be saved.

One of the most charming features of the old southern garden was its flowers. Except a few along the walk to the front door of the dwelling-house, all the flowers on the place grew in the garden proper. In the typical garden, roses arched the gateway; bushes of tumbling Snow-balls graced the corners; stately Pæonies lorded over the Pinks, and Tulips that bordered the walks; mocking-birds built and sang among the constantly blooming roses, and all the old-fashioned perennial flowers—many of them with quaint local names—were found following each other in their season. Looking backward through thirty years of hazy memories the old garden seems yet a place of ideal attractiveness—the abode of neatness and homely simplicity; the spot in which every member of the household took pride and delight.

Kittrell, N. C.

O. W. Blacknall.

In the Company of Trees.

IF one wishes to be taken into the intimate confidence of a great tree, and to get the full enjoyment of its strength and beauty, he should lie upon his back on the greensward beneath it, cross his arms under his head by way of pillow, and let the eye climb slowly up the mighty trunk from root to top-most limb. Thus have I lain beneath an ancient White Oak; thus watched the infinitely varied play of light and shade through the dense foliage; thus noted the delicate tracery of the leaves against the blue of the sky, and learned by heart each wrinkle of its rugged bark. This is the way to study the varying characteristics of trees, and to learn many a sylvan secret only revealed to the real lovers of nature, upon whom she has graciously bestowed eyes to see and the heart to feel her beauty and her mystery. I have spent a summer afternoon moving slowly from trunk to trunk, from Oak to Maple, from Maple to Sour Gum, from Gum to Walnut, and then to Ash, to Poplar, and back again to the old White Oak, most satisfying of all.

Sometimes the sun would smile upon me through an opening in the boughs, or a light-hearted vireo warble a lullaby; the orioles whistle plaintively; the friendly squirrels pretend to scold, and scurry away from branch to branch, only to hasten back to peep again and drop a tiny acorn on my cheek. The great white clouds sailing far overhead; a distant hawk leisurely cleaving the air on his strong wings; a few drops from a flying scud—all these become stirring incidents, fraught with healing and refreshment to the heat-worn nerves and weary brain of the house-dweller. Should the eyes close into delicious slumber the great tree stands guard over its puny visitor, filling one with a sense of security and of being cared for as by a mighty and gentle nurse.

Thus has it chanced to me to be overtaken by a summer shower, and to be awakened by the first cool splash of rain-drops upon my brow. The Oak had no need of mackintosh and umbrella; it was only necessary to turn the water-proof side of its varnished leaves uppermost, and stand quietly to take whatever came, strong in the security gained by a hundred years of storm and sun. The foliage of the tree protected its sleeping guest as long as possible, but now, with a gentle warning splash, the drops fell more and more quickly; little streams ran down the trunk, following the corrugations in its rough bark; the leaves twinkled merrily as they shed their burden of moisture in my face. Then the sun came out a moment, and the whole tree sparkled joyously like the countenance of a friend who is bringing you welcome news.

Rose Brake, West Va.

Danske Dandridge.

The Manufacture of Perfumery at Grasse.

A CORRESPONDENT of the *Gardeners' Chronicle* has written an account of an inspection of some of the flower distilleries at Grasse, from which we extract a few of the interesting facts.

"In the production of rose essence from 10,000 to 12,000 kilos of roses are needed to make a kilo (two pounds and a fifth) of the extract, which is worth 2,000 francs, or \$400. This is such a costly article that few firms can afford to handle it, and it is usually made only on order given a long time in advance of the time of manufacture in spring. The attar of roses made in Turkey is stronger than that made in Grasse, but not so fine,

perhaps, because the Turks have not such finely perfected machinery as that which is used in the Maritime Alps. Violets and Narcissus are cultivated by tons, only Parma violets being sent to the still, the others not being sufficiently odoriferous. These pale blue and fragrant violets are grown in the neighborhood, and according to the supply or demand, or according to whether it is a good or bad season, these choicest of modest flowers bring at wholesale from one franc to four francs a pound. Sometimes higher prices are paid.

"The best time to visit Grasse is, of course, in the advanced spring, when the general country is an undulating forest of flowers and the air is filled with a thousand odors. Visitors in the spring-time should be about as much as possible in the evening along the well-kept lanes which cross the flower reserves, for then the perfumes are the most powerful and the best appreciated. Situated on a gentle slope of a spur of the Maritime Alps, the view of Grasse and its vicinity is most picturesque, offering ever-changing prospects as the tourist ascends. On the summit of the hills, above the town, a magnificent view is presented of the numerous manufactories, all surrounded by flower-covered fields, a smiling valley beyond them, and a range of hills closing the view of the sea. When the flowers are harvested for the distillery they are brought into sheds, heaped on long tables, and women, who are so scantily paid that they can barely exist, are set to sort them. Old and young women, little boys and girls, all are at it and earn but a miserable pittance. On following the car-loads of flowers into the distillery, one will at first be pleased with the all-pervading perfume, but getting into the depositing sheds this becomes too much of a good thing. The odor is so rank as to lose its fineness, and it becomes only a strong, almost nauseating, smell, which permeates everything damp, even to the handkerchief within one's pocket."

Plant Notes.

Some Recent Portraits.

THE plants figured in the July issue of the *Botanical Magazine* are of less interest than usual to the gardener, who will see in them botanical rather than horticultural subjects. They are: *Synandropadix vermitoxicus* (t. 7242), a stout aroid of Tucuman, an east Andean province, where it inhabits hedges and shrubberies. This plant produces hastate-cordate leaves, and large cymbiform spathes with recurved margins, dirty green on the outer and pale purple on the inner surface, the tubers being described as attaining a weight of four pounds. In its native country it is known as "Cana brabo, the ferocious Cane," because the plant blisters the human flesh. *Disa incarnata* (t. 7243), a small inconspicuous flowering Orchid of Madagascar, and a member of a genus of which Mr. Bolus, who has paid particular attention to it, remarks that "in the variety of its perianth, it is only excelled, perhaps, by that of *Habenaria* and *Catasetum*, and is scarcely equaled by that of any other genus in the vegetable world." To this Sir Joseph Hooker adds, "that, after a careful study of a large proportion of the species of *Habenaria*, including upward of one hundred Indian, I find their flowers to be morphologically uniform as compared with those of *Disa*; nor does this remark apply to the perianth only, it extends to the column and its appendages, and even to the pollinia. I quite believe that if *Habenaria* had been a European genus, it would have given rise to as many genera as *Orchis* and *Habenaria* have—that is, about thirty-five instead of the five included in it by Bolus, and upon much more marked structural characters. From such a dismemberment *Disa* has been saved by its remote geographical position far from the haunts of systematic botanists, and by the sagacity of those orchidologists (Lindley and Bolus) who have devoted themselves to its study." *Gynura sarmentosa* (t. 7244), a climbing plant of the Senecio tribe of Composite, and a native of the Malayan peninsula and islands. It is described as a very elegant climber, with richly colored stems, branches, and involucre, although from its lax habit of growth not likely to become a horticultural favorite, except in tropical gardens, where space is at its disposal. The small flowers

are not attractive, although the habit of the plant, which is said to be the most graceful member of this rather coarse genus, may make it desirable. *Masdevallia leontoglossa* (t. 7245), a native of the mountains of New Granada, and a small, dirty flowered species. *Primula Forbesii* (t. 7246), a Chinese species, and one of the only two known Primroses which are strictly annual—that is, that die after first flowering—although they should, perhaps, be more accurately described as monocarpic rather than annual if, as is probable, they form seedling plants the first year and flower and die in the following. *P. Forbesii* is another of the species lately discovered in the mountain districts of the interior of China, where Delavay, the French Jesuit missionary, discovered it in marshy ground near Tali, in Yunnan. More recently, General Sir H. Collett has found the same plant in great abundance on the hills of the Shan States in eastern Burmah, growing at an elevation of three thousand feet from the sea. *P. Forbesii* is a delicate species, with small, long-stalked, ovate-cordate, irregularly lobed leaves, and small, long-stemmed, rose-colored flowers arranged in remote whorls.

A charming colored plate of *Acacia dealbata* gives special interest and distinction to the first number of the forty-second volume of *The Garden*, issued on the 2d of July. This is the Silver Wattle of eastern Australia, and one of the most beautiful trees brought from Australia. It is now a well-known plant in all semi-tropical countries, forming, where the soil suits it, handsome specimens fifty to one hundred feet high, and in spring flowering most abundantly. It is largely grown in southern France, especially in the neighborhood of Cannes, and a considerable industry is founded on the sale of its fragrant flowers, which are shipped to the Paris and London markets in large quantities. In California, too, it has been largely planted, and is one of the best Australian plants which have as yet been tried in that state, although apparently capricious about soil and location. At Cannes, for example, it is perfectly at home, while at Nice, a few miles distant, and in several other towns on the Riviera, it refuses to grow, owing, probably, to the presence of lime in the soil, which is distasteful to many Australian plants. A line a yard wide, it has been said, may be drawn between Nice and Cannes to mark the boundary of the territories in which this tree will and will not grow. In its native country it selects swamps and low ground, where it sometimes attains a height of one hundred and fifty feet.

New or Little-known Plants.

Corylopsis pauciflora.

AN account of some remarkable Japanese plants in Dr. George R. Hall's garden, in Bristol, Rhode Island, appeared three years ago (vol. ii., p. 537) in the columns of this journal. Dr. Hall was probably the first American intelligently interested in plants who lived in Japan, and he was the first to send Japanese plants to this country. He first visited Japan in 1860, and about ten years later began to plant Japanese plants in Bristol. Later he made another voyage to the east, and, returning in 1874, brought with him several plants, including a specimen of *Corylopsis pauciflora*. This (see our illustration on page 342) has now grown into the largest and most vigorous specimen that has come under our notice. The branches are six feet in height and form a compact mass of thirty-six feet in circumference.

Corylopsis belongs to the Witch Hazel family, and is chiefly valuable for the extreme precocity of the flowers, which appear in this latitude early in April, before the unfolding of the leaves; they are pale yellow and hang in short compact racemes, which quite cover the branches. Although less showy than the Forsythias and some other spring-flowering shrubs, *Corylopsis pauciflora* deserves a place in the garden, to which in early spring it adds interest and variety.

Cultural Department.

Fruit Notes.

THE Minnewaska Blackberry, I am sorry to say, must be discarded here, owing to its lack of hardiness. It is rather more tender than Kittatinny. Erie is a coarse grower and not hardy, and not certain to yield perfect berries. Agawam has a delicious flavor, and is the best home berry, with Snyder, for market—that is, in climates as cold as that of central New York. After continued experiment, my belief is, it is best to cultivate Blackberries two years, and as soon as the canes come up thickly let them fill the ground. After that I put in neither horse nor hoe. The canes must be topped and the old canes cut out. Unpleasant as handling Blackberry-bushes is, this

Cleveland as a berry not to be discarded; also in Lida, in Clara and Pearl, in Saunders, and in Parker Earle. Cumberland is still a standard for all soils and spots. Sharpless is unsurpassed on strong clay soils, but in some sections flavorless. Gypsy is an ideal for quality, but medium in size. Haverland must be retained for size and prolific bearing. Wet weather makes it soft, and it hangs over to the ground too closely. Princess I only get a taste of, but I believe in it. Yale and Williams are promising. The wonders with me are Thompson's 51 for size and length, a veritable lady-finger; a seedling of my own for double flowers, and yet large rich fruit, not prolific; Parker Earle for quantity. Those who do not care to experiment can stick to Haverland, Cumberland, Bubach and Sharpless for large fine fruit.

It is a good time to lay plans for experiments, save seeds of

Fig. 59.—*Corylopsis pauciflora*, in Dr. Hall's garden, in Bristol, Rhode Island.—See page 341.

reduces the disagreeable job to a minimum, and gives me the largest crops.

I am inclined to modify somewhat my previous judgment of the Lucretia Dewberry. I now grow it on trellises of two wires, two feet and four feet high, and lay down the vines for the winter. This practice is almost identical with Grape-culture. They have no canes, but are true vines. The crop is magnificent for size of fruit, quantity and quality. Grown carelessly the plant is useless.

Of all Raspberries I see nothing as yet equal to the Shaffer. It always winter-kills somewhat, but it always gives fine crops of mammoth berries. But the real point is quality. This is the best berry for canning, for cooking, for jellies, for jams. The color is against it with some people. I am growing a large number of seedlings from it.

We are much in need, even yet, of thoroughly good black raspberries as large as the Gregg and absolutely hardy.

In my Strawberry-beds I renew my confidence in Mrs.

choice things and grow a few rows of seedlings. It may not pay, but Mr. Fay has made over \$25,000 as his share of Fay's Currant. You will be sure to get lots of pleasure and character from experiments.

I am in receipt of letters from Japan and from Corea about what are called Japanese Persimmons. Mr. Baird, of Fusan, Corea, says the most northern sorts will probably prove hardy here as far north as Philadelphia. I hope for better than that. Mr. Loomis, of Japan, thinks we can get seedlings that will be hardy as far north as central New York. He has sent seeds to Parsons & Co. for a full test. Dried Japanese Persimmons far surpass figs and dates. At this place I have native Persimmons from seed growing, and absolutely hardy. I have grafted successfully with best sorts grown by the best horticulturists in Virginia and Missouri. The chief trouble is in restraining cions from the south from budding out too soon, as the Persimmon is one of the latest of all trees to start growth in spring.

I recommend in all culture to use a note-book, and not rely on labels and stakes. These, with all precaution, get displaced; but your book is secure. It can also be referred to in the house at any time. It is only necessary to number your rows, and then write down in columns the names of varieties as planted.

The cost of covering Cherry-trees with mosquito-netting against birds is as follows: For fifteen trees in 1891, about \$8.00. The crop was largely used at home, but I sold \$30.00 worth. The netting will last two years. The fruit can be kept on the trees all summer.

As an all-around superb red grape for everybody's growing I recommend Gaertner. It is a rapid grower, large grape, large bunch, fine color, first-class flavor and sets admirably. Brighton must be grown with others, to pollinize it; otherwise it would stand at the head of red Grapes. Lindley is another splendid red that fails to take care of itself. Woodruff I still am sorry to condemn as too poor on my ground to be ranked among the best Grapes.

Clinton, N. Y.

E. P. Powell.

Notes on Shrubs.

IT is probable that very few people, even among those who are botanists, ever see mature fruit of the Leatherwood (*Dirca palustris*), because, although it is not so very small, it is not conspicuous, being hidden among the light green abundant foliage, and it ripens, falls, and is lost before it might be expected to have attained full growth. In this latitude, and in warm situations, the fruit ripens about the tenth of June. It is about one-third of an inch long, egg-shaped or top-shaped, and two or three are usually produced on the same stalk, which is rarely over half an inch in length, and often much shorter. The outer covering of the fruit can hardly be called fleshy, being leathery and exceedingly thin. At maturity, the fruit is of a pale whitish green color, and is so easily detached from its stalk that it is liable to fall at the slightest touch. After it does fall, or when drying for the herbarium, the outer covering of the seed turns black. If on the ground, the outer covering usually decays and falls away, and exposes the smooth shining brown, and very thin and fragile shells or seed-coverings beneath. The seed of the Leatherwood is usually produced in considerable abundance, and as it germinates very easily any number of plants are readily produced. It does not seem to be known whether or not the seed is ever taken for food by birds or the smaller quadrupeds, but in the Arboretum seedling plants are often found in most unexpected places.

Aside from its foliage and general aspect, the Leatherwood may be known at this season, from all other native shrubs, by its very soft and pliable branches and tough bark, by the base of the leaf-stalk entirely covering and concealing the brown, velvety buds which are to continue the growth next season, and by each annual growth of the branches appearing as if jointed, a characteristic which is given by the conspicuous circular leaf-scar. It will also be noticed that the last leaf or bud does not terminate the shoot at the end of the season's growth, but that there is a little budless tip, or point, which is really the apex. Except for its yellow flowers, which are among the earliest to appear in spring, the Leatherwood is of no great ornamental value from a decorative point of view.

Of all the species in the collection which are broadly included under the genus *Prunus* the earliest to ripen fruit this season proved to be the pretty flowering *P. pendula*, which had small, ripe, shining black cherries by the middle of June. They did not all mature at once, more than two weeks passing before all had changed color. The fruit was produced in much greater profusion this season than is usual here. These cherries are too minute to be of any economical value, but what there is of them has a pleasant flavor, a fact which was appreciated by the birds and chipmunks, which greedily carried them off even before they were fairly ripe. The kernel is also pleasant to the taste, which is in striking contrast to the bitter acrid-tasting kernel of our native little wild Red Cherry (*P. Pennsylvanica*), which is usually left by animals as long as there is an abundance of more palatable food. The wild Red Cherry here begins to ripen about the first week in July. Although these bright red cherries are small, being hardly larger than peas, they are a good deal larger than those of *P. pendula*. They are attractive in appearance, but the flesh is sour and not agreeable to the taste.

P. tomentosa, which came to us eight or ten years ago as seed, which was collected in the mountains about Peking, China, gives more promise of becoming a real acquisition among wild fruits of economical value. It has produced

cherries during several seasons, but never so abundantly as this, although even this year all the plants did not bear a large crop. Like most other seedlings of fruit-trees, these show much variability in quality of fruit, but on the best plants the fruit is of a pleasant though slightly acid flavor, and is over half an inch in diameter. It is round, of a clear, light red color, and is produced on stalks which are just long enough to attach the fruit to the branch, perhaps an eighth of an inch being about the average length. It is a Cherry which seems capable of much improvement by selection and cultivation, and as it is thoroughly hardy it is quite likely to obtain and keep a place in northern gardens. Professor Budd states that it is quite hardy on the grounds of the Agricultural College at Ames, Iowa. It blossoms so early, however, that although the flowers are always abundant they are so liable to be injured by frost that a good crop of fruit is not always assured. The fruit is sparsely covered with short hairs, which are so slightly noticeable that the edible quality is not affected. The flesh is firm though juicy, and the kernel is sweet and without any bitterness or suggestion of prussic acid. While the first of the cherries were ripe in the last days of June, the crop may be said to have only now (July 12th) reached perfection.

This species is interesting because so different in habit from all other Cherries in common cultivation. It may be likened to a great overgrown Currant-bush more than anything else. A number of stems spring from the root, and they appear to have about reached maturity at seven or eight feet in height, and at this time the bushes have a spread of ten or twelve feet or more. Wherever the branches rest closely upon the ground they form roots freely, and practically become independent plants. This tendency to form roots should render the propagation of any desirable superior form a matter of easy accomplishment either by layers or cuttings instead of by grafting, which in cases like this is to be avoided whenever possible. This little Cherry may prove to be a good stock upon which to graft other Cherries when a good stock is wanted for dwarfing purposes.

P. Grayana, a northern Asiatic species, which the eminent Russian botanist, Maximowicz, named in honor of the late Dr. Gray, has borne a few ripe fruits this season, undoubtedly for the first time in America. It closely resembles the Bird Cherry (*P. Padus*) of Europe, and has flowers and fruit in long racemes, the fruit being black and smaller than the cherries of our common Choke-cherry (*P. Virginiana*), and with a much less agreeable flavor—in fact, it might be counted decidedly puckery and disagreeable.

A peculiarity of *P. Grayana*, as also of *P. Padus*, is the extreme earliness of the foliage, the plants being covered with well-developed light green leaves, which render them conspicuous before the middle of April and before the leaves of other trees and shrubs have made much headway. The earliness of the foliage may be considered the chief ornamental value of these trees in this country. Unfortunately, also, they appear to be extremely subject to attacks by the black-knot fungus.

Arnold Arboretum.

J. G. Jack.

Cyclamens and Chinese Primroses.

THE well-known varieties of *Cyclamen Persicum* and *Primula Sinensis* are among the most useful dwarf-growing plants for conservatory and house decoration during the winter and spring, since their profusion of flowers is most welcome at that season. Of course, it is now too late to sow seeds of *Cyclamen* for the coming season's flowers, but about September will be a good time to make such preparation for the following year, for it is far more satisfactory to raise a crop of seedlings each season than to keep over old plants, which will not produce such fine flowers under ordinary cultivation as the young seedlings. The seeds should be fresh, as they lose vitality quite rapidly. The safest method is to sow them in pots or pans of light soil as soon as they are ripe. The pots should be shaded from the sun and placed in a temperature of fifty-five to sixty degrees. As the seedlings appear they should be given plenty of light to induce a sturdy habit, but they should be protected against strong sunshine. As soon as they have two or three leaves they may be transplanted into two-inch pots, light loam being a suitable soil for this purpose, to which may be added some sand or brick-dust to make the mixture more porous. When the young plants are nicely rooted, and before they become badly pot-bound, they should be shifted on into three-inch pots, and from these into four and six inch sizes as they require it. The plants do not like to have the soil very firm about the roots, and therefore light potting should be the rule at all times, and this is one secret of success in their

cultivation. Manure may be used in the compost in reasonable quantities, but should be old and thoroughly rotted. During the summer months *Cyclamens* can be well grown in a frame outdoors, giving plenty of fresh air at all times, but keeping sash over the plants to protect them from heavy rains and strong sunlight. As soon as the nights become cool, however, the plants will be benefited by bringing them into the greenhouse. Under this treatment strong-blooming plants are produced in fifteen to eighteen months from the seed. As green-fly is a prevalent pest of *Cyclamens*, fumigating may be necessary occasionally, but otherwise the plants are not specially subject to the attacks of insects.

In the matter of varieties it is probably best to secure some seeds of a good strain from some reliable seedsman for a beginning, and then, by careful selection and crossing, the strain may be still further improved by the grower.

The Chinese Primrose now presents a wonderful variety of forms, as the result of many years' careful selection and fertilization by various specialists, and the colors range from white through the various shades of purple to almost a blue, and from pale pink to scarlet and crimson. The single varieties are readily procured from seeds, while those with double flowers must be perpetuated by means of cuttings and division, and among the latter the double white form should not be forgotten, for it is of neat habit and extremely prolific in flowers, the latter lasting very well when cut.

The Primulas, in general, are a shade-loving class of plants, and *P. Sinensis* is no exception to the rule, but in regard to soil they are perhaps less exacting than their relatives the *Cyclamens*, and almost any light, sandy soil will produce fair results. In general treatment a similar plan may be followed to that outlined for *Cyclamens*, but it should be remembered that the Primulas do not require much water over the foliage, though an abundance at the root when in active growth, and, as the flowering period approaches, some weak liquid-manure will be found beneficial.

Holmesburg, Pa.

W. H. Taplin.

Perennial Larkspurs.

AFTER a long waiting and vexatious experiences with seed, *Delphinium Zalil* is now in flower in the garden, where it was planted in the spring of last year. This novelty is one of Dr. Aitchison's discoveries in Afghanistan, and when first described as a lemon-yellow Larkspur hardy-plant lovers were all asking for it, but as it was distributed by means of seeds, and these germinate only when fresh-gathered, many were the disappointments. Our own plants are from fresh seeds kindly sent me by Herr Max Leichtlin in the fall of 1890. These germinated readily, and were wintered over in the greenhouse and set out in spring, where they grew freely for a time, and then disappeared to come up vigorously again and flower this year. I mention this as a recognized authority has described *D. Zalil* as an annual, which it certainly is not, neither could it be called a biennial, for, supposing that the plant completes its existence after flowering, of which I am not sure, even then it takes more than two seasons' growth to get it strong enough to flower. *D. Zalil* belongs to a section of *Delphiniums* which has many representatives in the United States—namely, those that spring from a fleshy root-stock and die down as soon as seed is matured to spring up again the following year. These are not well known in gardens, though some are well worthy of cultivation, such as *D. tricornis*, which is widely distributed through the southern and western states. *D. azureum* is another species of which the same may be said. The specific name of *D. Zalil* is the native name. Since a yellow die is extracted from the roots in Afghanistan, another name, *D. sulphureum*, was given the plant when first distributed, but *D. Zalil* has priority, though the synonym describes the color accurately. With us the plants are three feet high, with much-branched flower-stems, while the flowers resemble those of *D. cardinale* and *D. nudicaule* in shape. The habit of the plant is slender and the foliage very finely divided; more so than in any other known species. As a garden-plant *D. Zalil* is insignificant compared with the beautiful double forms of the garden Larkspur, and would be passed by without remark by many, still it is of much interest to those who love for other qualities than mere showiness.

While on the subject of *Delphiniums*, has any reader had experience with the Larkspur disease, or smut? It attacks the flower-spikes and completely blackens them, in some cases crippling the unopened flowers so that they never develop at all. It is getting to be a question here whether we can have Larkspurs or not. Two years ago there were infected plants in the garden that were purchased, and in this way the disease

was introduced. These were all destroyed, and a new lot raised from seed, and this year it is apparent in many plants again, and my experience teaches that next year Larkspurs will be a complete failure here. The old reliable, *D. formosum*, is as liable to it as any others of garden origin. This smut has much the same effect as that which attacks the Corn, and is probably an allied species. Certainly the disease should be investigated by some mycologist.

D. Cashmirianum is a species that is perfectly hardy and distinct from all others. It has dense panicles of large flowers, but the color is not a pleasing one, being a dull purplish blue. It is not very desirable as a garden-plant except as a single specimen. A short time ago a so-called white form was distributed, and this proves to be of a decided greenish white, and even less attractive than the typical plant.

Too much cannot be said for the Larkspurs of garden origin, especially the double varieties, and it is worth repeating, now that they are in flower, that if the double varieties are marked when in bloom, and seed saved from them, this will produce fully seventy-five per cent. of double-flowered plants. Named varieties are very short-lived, as hardy-plant dealers know, and have to be reimported often from Europe, as they cannot be raised true from seed, and, indeed, seed is but sparingly produced from double flowers, but the seedlings are usually strong enough and able to withstand the climate here where the parents fail. Larkspurs are gross feeders, and need a rich soil that never dries out, and therefore the heavier the soil the better. In a damp position they will grow six to eight feet high, with long spikes of flowers, which may be cut as soon as they fade, and another crop of flowers will come on later. Seedlings flower the first year, but do not attain full strength until the second season.

A word should, perhaps, be added with regard to *D. Przewalskianum*, now in flower for the first time here. It was sent out a year ago, and grew vigorously last summer and wintered out well, and is now about four feet high, with spikes of pale creamy white flowers that are small, and in no way attractive from a garden point of view. The foliage is ornamental, being prettily cut, of a deep green, spotted with a paler green. It is of Asiatic origin, and, like a species from Yunnan grown last year, without name, is rather disappointing.

South Lancaster, Mass.

E. O. Orpet.

[We have received specimens of the diseased *Delphiniums*, and the trouble seems to come from a mite and not from a fungus. Professor Halsted thinks that if the affected plants are wet with cold water the increase of the mite will be checked.—Ed.]

Melianthus major.—This is a half-hardy greenhouse shrub which seldom fails to attract attention. Glaucous-leaved plants seem to possess attractions for most persons, but when the foliage is beautifully cut, as in this plant, it possesses a double beauty. There is no plant in the garden of which the name is so frequently asked as this, from which I presume that it is not often grown, though it was introduced many years ago. It is useful, not only as a specimen plant in the greenhouse, but also in the open, in sub-tropical borders, where its peculiar distinctness proves very attractive. It forms a plant some four feet high, with smooth, hollow stems, leaves stem-clasping and acutely cut.

Jatropha podagrica.—A New Granada plant which seems to be better entitled to the common name of Coral-plant than the *Erythrina*, as its inflorescence bears a striking similitude to a bunch of red coral. In all respects, this plant is a curiosity of vegetation. It is euphorbiaceous and requires the cultivation usually given to that family. It grows readily from seed, and forms smooth, erect, club-like stems, quite rounded at the apex, from which spring large, smooth peltate-cordate leaves. The plant becomes dormant late in the year, and as the new leaves commence to move there is thrown up from the apex of the gouty stems a long scape topped with an irregular raceme of orange-red flowers, arranged as a spray of coral. This inflorescence continues about a month.

Geranium Henry Cox.—Some few years ago, when visiting Mr. John Thorpe's place, I happened to meet an intelligent gentleman who was devoted to fine *Pelargoniums* in general, and this variety in particular. Having become interested in his experience, I took pains to secure a plant of the variety, which proves a most interesting one with beautiful leaves, when properly grown. It belongs to the golden tricolor section, and is properly a greenhouse-plant, being a very weak grower, very dwarf and slow to increase. It seems to need

very careful cultivation, and should be kept in warmth near the glass. In such conditions it puts forth very high-colored leaves, with veins of yellow, scarlet, green and cream of the most vivid tints. The stems of the plant are white, and a well-grown specimen is a charming thing, besides being a credit to a very skillful cultivator.

Linaria cymbalaria.—The Kenilworth Ivy is not usually known as a hardy plant, but, like many others, if grown outside under proper conditions, it will live through an ordinary winter. The conditions seem to be that it shall have a sheltered place entirely free from wet. Some plants under an overhanging south wall lived over last winter, and I have several times seen this fact noted by others. If any one had an old wall to furnish with plants it would be well to try this, as it is easily established in summer, and probably if the plants were killed in a severe winter there would be seeds scattered in the recesses which would rapidly germinate and keep up the stock.

Berteroa mutabilis (*Alyssum mutabile*) is an herbaceous perennial introduced by Thorburn & Co. last year, which is just now in flower. It proves to be perfectly hardy, and forms low spreading plants one and a half feet high, many-branched, and furnished sparsely with white *Alyssum*-like flowers. The foliage is dull and not especially attractive, and from scarcity of flowers the plants have a weedy look, and do not seem a desirable addition to the garden.

Ipomœa Bronsoni, another introduction of Messrs. Thorburn & Co. of last season, is said to be a Cuban *Ipomœa*, and is a most wonderfully rapid-growing vine. A strong plant last season covered a great number of square feet of space, and it is doubtful if there is in cultivation an annual vine which makes more rapid growth. The plants are white-stemmed and gouty at the base, but the season was not long enough for the production of flowers. This is probably of little disadvantage where such a plant would be most useful, as most of the quick-growing vines are apt to produce seeds which stock the garden with plants to be weeded out.

The Forest.

Our Land Office System.

A FEW weeks ago we quoted part of an interesting chapter on the Forests of Minnesota, which had been prepared by Mr. H. B. Ayres for the Nineteenth Annual Report of the Geological Survey of that state. In the same chapter Mr. Ayres makes some excellent observations on our Land Office System, which we reproduce below:

While the giving of from 300,000 to 4,000,000 feet of standing Pine to a poor pioneer seems a paternal act on the part of the Government, the actual result is putting nearly all the value of the timber into the pocket of the lumberman, to whose plant the tract may be tributary.

The settler, even when honest, can, as a rule, afford to live on a Pine claim merely long enough to comply with the homestead or preemption law, and when he sells his Pine, often gives title to the land also, when it starts upon the routine by which it is, eventually, advertised for taxes, non-productive, idle, worthless.

If we continue, as we have done, the 17,000 men now employed in reaping the great natural harvest will soon leave the country, as they have left the older lumber states; for the lumberman, under the present system of disposing of public lands, cannot think of waiting for a second growth, while he can acquire new forests of standing Pine at a nominal figure. His only sensible course, as far as his own interests are concerned, is to strip off the lumber and abandon the land.

The time to decide upon the use to which timbered lands should be put is, undoubtedly, before they pass into the hands of individuals. They should be examined, and the question decided, whether they should be thrown open for settlement as farm-lands, or whether it would be best for the general welfare to have them kept in timber.

There are still in the state some 6,000,000 acres of more or less wooded land belonging to the Federal Government. To one looking the situation fairly in the face, would it not seem best to have all this area withheld from settlement until the soil be examined, and its adaptability determined?

The direct profits that may be expected from forestry are not large after the virgin timber has been cut. In Europe, seldom over 5 per cent. is realized, and the American lumber-

man cannot be expected to act contrary to his notable common sense and shrewdness and stay and do a business that brings in 5 per cent., while he may by entering a new field, under the present land office system, get from 10 to 200 per cent. Only in exceptional cases, most favorable to growth and convenience to market, is forestry profitable to the individual. To a corporation of woodworkers the profits may be greater, but it is only the state or the General Government that will be able to reap all those other benefits, such as permanency of industries, support of greatest population, etc., which, added to the direct profits possible to the individual, would bring the sum of gains well within the percentage of fair business profits.

Forest-lands should, therefore, as a rule, be managed by the state or by the Federal Government.

In Minnesota, the federal lands now vacant, and more or less wooded, amount to some	6,000,000 acres.
The state lands	600,000
The university lands	470,000
The school lands	231,000
	1,301,000

Total public forest-lands . . . 7,301,000 acres.

The question as to what would be the best management of these lands has been studied, and studied faithfully, by many, if not by all the men upon whom their care devolved, and, no doubt, they have found the difficulties that they, single-handed, were unable to overcome. It is necessary that all the people be so well informed that they may, at least, be able to appreciate the efforts their chosen representatives in the local, state or Federal Government may make in their behalf; and while it is the plain duty of these representatives to study all the questions bearing upon the welfare of their constituent regions, these questions are so numerous that they cannot be expected to master them all, unless those who have made special study aid them by digests of their work.

Correspondence.

Plant Diseases in West Virginia.

To the Editor of GARDEN AND FOREST:

Sir,—In the southern portion of this state, especially in Mercer County, this season, the indigenous Juniper, and particularly those in yards, have much the appearance of fruiting Orange-trees, so thickly are they dotted with the large cedar-apple (*Gymnosporangium macropus*) in its fruiting stage. The orchards of this district plainly show the predominance of this fungus by the prevalence of the second stage (*Roestelia pyrata*) on the leaves of the apple. The farmers questioned state that the disease has been noticed particularly upon the Juniper-trees during the last three years. Previous to my visit, no attempt whatever had been made to cut out the cedar-apples and burn them.

The leaves of the wild Blackberries, especially those of pasture and meadow lands, are being destroyed in all sections of the state by the *Uredo*, *Cæoma luminatum*, which is so common this season that I have yet to see a field in which the briers were not more or less affected by this fungus, while many present the appearance of being covered with an orange fabric. In this state, where these briers are considered one of the worst of our weeds, the benefit of such widespread affection can be readily realized.

I have been watching with considerable interest for the appearance of *Puccinia suaveolens* among our few stations of Canada Thistles, but have so far failed to notice it. Once only have I found the disease, and then on the Boar Thistle (*Cnicus lanceolatus*); even this was so far from any known patch of Canada Thistles that I was unable to transfer the spores, much as I desired to do so. I feel confident that this would be the only true measure of eradication to practice effectively against this Thistle. I was glad to be able to prove last season that the seeds produced by Canada Thistles in this state were incapable of germination, owing to improper fertilization of the ovaries. There remains, therefore, only the root-spreading for our farmers to contend with.

In the Pine-forests of the Alleghany region great damage is being done by a beetle (*Dendroctonus frontalis*), which girdles the inner bark, thus cutting off the flow of sap. Hundreds of trees are perishing through the destructive action of this insect. In searching for some method of checking its ravages, our entomologist, Mr. A. D. Hopkins, found large numbers of the larvæ of this beetle dead and covered with a new fungus disease which Professor Peck has named *Cylindrocalla*

Dendroctoni. Detecting no other cause for the death of these larvæ, and deciding that the *Cylindrocalla* must be the agent, we have inaugurated a series of experiments to decide the question, and, if possible, to enable us to cultivate and transmit the disease. Trees affected and unaffected by the beetle in question were found to be very prominently the host of *Lophodermium Pinastris*, *Coleosporium Senecionis*, and *Hyphoderma Dezmanzieri*, but we consider none of these forms to be particularly devitalizing to the affected trees.

The Laurels are greatly affected this season by the common leaf-spot (*Septoria Kalmiaecola*); and the leaves of *Rhododendron maximum* in the dense forests of the Alleghanies are being badly deformed and the shrubs injured by great quantities of *Exobasidium Rhododendri*. We believe this to be the first report of the presence of this European species in the United States. Our Peach-trees in many localities are showing this season disastrous inroads of the Yellows, and in spite of our efforts among the farmers of the state the Black Knot of the Plum and Cherry is advancing.

Our state began botanically terra incognita, our work is becoming fruitful of new forms and exceedingly interesting in general. Many of our wild plants, economic and otherwise, are affected this year by different parasitic species of fungi, and our orchards and crops are in nowise exempt from their almost discouraging attacks.

How Cold Air Settles in Hollows.

To the Editor of GARDEN AND FOREST:

Sir,—An extreme instance of the often-observed fact that cold air settles in hollows, will bear repetition, although it occurred as long ago as the winter of 1874-75, and the facts were made public. At the time, in the Traverse Bay region, Michigan, there was considerable interest manifested by fruit-growers in the subject of the proper location for orchards, and the highest elevations were considered the safest.

Mr. Isaac Garthe, living near Northport, Leelenaw County, arising before daylight on the 10th of January, 1875, was surprised to find his thermometer indicating thirty-six degrees below zero. He at once started for the house of his next neighbor, Mr. Theodore Parmelee, whose house is 150 or 200 feet higher, and on the way noticed the steady rise in temperature, which at his destination was up to sixteen degrees. After some minutes of conversation he returned home, and when he got there, still before daylight, the thermometer had fallen back to thirty-six degrees.

Mr. Garthe's house was in a hollow surrounded by hills, and it is hardly necessary to mention that the air was still. As sixteen degrees is about an extreme temperature for that region, this great difference of twenty degrees is rather noteworthy.

Milwaukee, Wis.

C. L. Mann.

The Rose Hill Nurseries.

To the Editor of GARDEN AND FOREST:

Sir,—This establishment is located at New Rochelle, New York, and has a wide fame for fine plants which have long been specialties here. Messrs. Siebrecht & Wadley have a reputation in New York City and Newport as leading florists and decorators, and also for their enterprise and activity in giving many flower-shows both in the Eden Musée and Madison Square Garden. The nurseries are probably the natural result of a long-continued successful city business with its demand for high-class flowers and plants, but there has been a branching out in other lines, so that an extensive list of plants is now grown here. A study of their beautifully printed and comprehensive catalogue led me the other day to New Rochelle, a section of Westchester County, where all the available lands seem to be undergoing a rapid transformation into syndicated parks. To the Rose Hill Nurseries is a short drive over a pleasant road, along which, on a quiet bit of road-side, I was surprised to find a rather imposing marble monument to Thomas Paine. How many people in this city know that the author of "The Rights of Man" has been honored in this way?

The entrance to the nursery is at present an excellent example of bold and careful planting. A long curving line of shrubs, hardy perennials, *Retinosporas* and other conifers, and bold grasses, backed by a Privet-hedge, shut out of view the main plantations, while groups and lines of bold plants at the left mask the base of Mr. H. Siebrecht's residence and partly hide the buildings in the rear. A noble group of *Rhododendrons*, at the extreme left, break the continuity of the screen. A border of this character, not overcrowded, is always

interesting, and not nearly so expensive to maintain as a border of ordinary bedding plants. Hardy plants are largely grown, several acres being devoted to their cultivation. I noticed not only a large selection of the popular hardy perennial plants, but also many gems in the way of terrestrial Orchids. There were also plantations of young Roses, others of *Rhododendrons*, Azaleas, Lilacs for forcing, while, as anti-climaxes, there were tanks of aquatics and borders of Cacti.

While the exigencies of nurseries require that they shall be located where land is comparatively cheap and the air is pure, it will usually be noticed that the florist generally locates in pleasant quarters where there is a good outlook. The Rose Hill Nurseries make no exception to this rule. The extensive ranges of houses occupy the ridge of a low hill from which there is a pleasant view over the surrounding country. In these ranges, mostly practical working houses, was found an extensive stock of plants. Messrs. Siebrecht & Wadley are large operators in Palms, which in these days are in such rapidly increasing demand for house decoration. Not only are Palms grown largely on the premises, but a branch nursery is maintained at Dabadie, Trinidad, West Indies, to which young plants are sent to be grown in the open to salable sizes. The traffic back and forth of Palms, Crotons, Marantas and various large-growing tropical plants is sufficiently extensive to enable Messrs. Siebrecht & Wadley to permanently engage a special compartment in the regular steamers for this purpose. The demand for Palms is evidently unending, for, not considering the Trinidad stock, here were to be seen Palms not only in special houses, but also in all available spaces, while extensive ranges of high frames were filled with small potted Palms, plunged in spent tan and kept close in the process of forcing. Among the showiest plants in the Palm-houses were some large specimen Crotons from Trinidad, in which climate they form small trees of brilliant foliage. Orchids are also a great specialty, a very extensive variety being grown. While numerous rare plants are often in stock, very large numbers of the useful Orchids are grown for cut flowers, it being necessary in the retail business to have always at command a constant supply. The flowers seem to be kept cut rather closely, only a few flowers of *Cattleya Gigas* being open during my visit. A rather novel sight was one house the entire half of which was occupied by a bed of *Odontoglossum crispum* planted out. These were on a sloping bed with a slatted bottom. Under this a bench was filled with clinkers to retain moisture. A Rose-house or two, one of *Chrysanthemums* and several of select Ferns were interesting.

The demand for Tuberous Begonias has found Messrs. Siebrecht & Wadley prepared with a strain in which they take great pride. The plants in flower in one of the houses were single and double, and excellent examples of this favorite flower. In the same house were some *Gloxinias* of an excellent upright flowering habit and most glowing colors, evidently a first-rate strain. Aside from these, the most brilliant mass of color in the houses was a collection of fancy *Caladiums*, which at this season are in their glory.

Such establishments as the Rose Hill Nurseries prove the existence of more active purchasers of good plants than we are apt to think are among us, but it would seem to require an exhibition building to house some dormant Tree Ferns some fifteen and eighteen feet high, a number of which I noticed as just arriving.

Mr. Siebrecht is ably seconded in the management by his two sons, and it is a pleasure to note the air of prosperity and organization evidently prevailing at Rose Hill.

New York.

Recent Publications.

The Silva of North America: A Description of the Trees which grow naturally in North America, exclusive of Mexico. By Charles Sprague Sargent. Illustrated with figures and analyses drawn from nature by Charles Edward Faxon, and engraved by Philibert and Eugène Picart. Vol. IV. Rosaceæ-Saxifragaceæ. Large quarto; pages 141; plates fifty. Houghton, Mifflin & Co., Boston and New York.

The fourth volume of this great work upon the trees of North America sustains the noble character of the preceding volumes, and adds another monument to the literature of American descriptive botany. The present volume will undoubtedly prove to be the most important of the series in a horticultural sense, for it discusses the Rose family, being largely occupied with the native Plums, Cherries, Apples and Hawthorns. The only other volumes which can approach it in horticultural importance are the forthcoming one devoted to the conifers and the one already published which describes

the Magnolias. Of the forty-one species described in Vol. IV. thirty-two are already in cultivation for fruit or ornament, and all the remaining nine are worthy of introduction. The volume also possesses unusual interest for botanists from the fact that it illustrates so many species bearing fleshy fruits, parts which are not preserved in the ordinary herbarium.

The greater number of the species fall into three genera—*Prunus*, with fourteen species; *Cratægus*, with the same number, and *Pyrus*, with five species. Other genera are *Chrysobalanus* (the Cocoa Plum), *Vanquelinia*, *Cercocarpus*, *Heteromeles*, *Amelanchier* and the single arborescent saxifrageous genus *Lyonothamnus*.

The most striking feature of this fourth volume is the portrayal of the native Plums, which have never before been so well presented, and which are now attracting great attention as the sources of a new class of fruits. Five species are now recognized in the eastern states where a few years ago there were but two. Four of these are the parents of important cultivated varieties, and all of them possess merits as ornamental plants. The one species whose fruit has not yet been ameliorated is *Prunus Alleghaniensis*, a slender small tree, which "is not known to grow spontaneously outside of a small elevated region in central Pennsylvania." This species was first described by Professor T. C. Porter in 1877. It is not known to cultivation except in a few collections connected with public institutions. As grown at Ithaca, New York, it is very showy when in bloom, and its foliage is attractive; and Professor Sargent says that the fruit is collected in large quantities in its native localities for making jellies, jams and preserves. We shall hope to soon see it generally distributed in the gardens.

The remaining north-eastern Plums are *Prunus nigra*, *P. Americana*, *P. hortulana* and *P. angustifolia*. *P. nigra*, the Red or Canada Plum, has not been recognized in our modern books, although it was described something like a century ago. Professor Sargent uses the name to designate a large-fruited, flat-stoned Plum, with glandular-serrate calyx lobes and glandular leaf-stalks, which ranges through the St. Lawrence valley, and westward to the Assiniboine region. Its flowers are earlier and larger than those of *P. Americana*, with which it has been formerly united; and it is thought to have been commoner in cultivation in former years than the other species. It is now said to be naturalized about houses and highways in some of the northernmost eastern states. To this species, Professor Sargent would refer the Purple Yosemite, Quaker and Weaver Plums. The separation of *P. nigra* from the older species, *P. Americana*, will excite a closer study of our northern wild Plums, although there may still be some doubt as to its true specific position. The separation of this species takes the true *P. Americana* from Canadian territory, and makes its northernmost limit, in the east, central New York and northern New Jersey. It ranges westward to Montana and Colorado, and southward to Florida and Mexico. The orchard varieties known as De Soto, Itaska, Forest Garden, Louise, Minnetonka, Cheney, Deep Creek and Kickapoo are referred to this species; and so are Forest Rose and Miner, but this is evidently an inadvertence, as they are also referred to *P. hortulana*, to which they probably belong.

The greatest innovation among the Plums is the recognition of a newly described species, *P. hortulana*, standing between *P. Americana* and the true Chickasaws. This species grows wild in the Mississippi valley, from northern Illinois to Tennessee and Arkansas, ranging southwestward through Texas. It is a smooth-growing, mostly upright, small tree, with ovate-lanceolate, mostly shining, closely serrate leaves, and reddish or yellow fruit, and a small roughish clinging stone. Horticulturally, it is probably the most important of the wild Plums, having given to cultivation the Wild Goose, Wayland and Miner, the three best-known native varieties; it is also considered to be the parent of Cumberland, Indian Chief, Garfield, Sucker City (evidently an error for Sucker State), Missouri Apricot, Indiana Red, Golden Beauty, Forest Rose and Parsons. It also appears to hybridize with the Peach, as in the so-called Blackman Plum, but these hybrids are sterile. The fruit, as represented in the plate, is rather undersized, and it lacks a peculiar dotted character which is common to most, if not all, the forms of this species.

The Chickasaw Plum, for which Marshall's name, *P. angustifolia*, is now used, is considered to have given to our orchards such varieties as Pottawatamie, Jennie Lucas, Early Red, Caddo Chief, Transparent and Colleta. It is essentially southern in its range, although it occurs as far north as Delaware and Kentucky. It is thought that this Plum has been introduced into the eastern states, if not into the United States as a whole; but this point, probably, needs close investigation. A peculiar character of the fresh fruit of this species

is the dotted surface, a feature which does not appear in the plate.

Among the Cherries, botanists will miss *Prunus demissa* of the west, which Professor Sargent considers inseparable from the Choke Cherry (*P. Virginiana*).

In wild Apples, the reader will find a variety (*Iceensis*) of the common Crab (*Pyrus coronaria*). This variety, which has been thought to deserve specific rank, is the common Crab of the Mississippi Valley. One of its distinguishing characters is the short and thick fruit-stem, as compared with *P. coronaria* proper, and which is not well indicated in the plate. *P. angustifolia* and *P. rivularis* are figured and described, as are also the two Mountain Ashes (*P. Americana* and *P. sambucifolia*).

Next to the Plums, the Hawthorns are the most striking feature of the volume. The magnificent plates will greatly aid in elucidating one of the most confused genera in our flora. Fourteen species are recognized, but there are few changes in nomenclature. *Cratægus uniflora*, of Muenchausen, replaces the familiar *C. parvifolia* of our manuals; *C. coccinea*, var. *mollis*, is erected to specific rank under the name of *C. mollis*; *C. rivularis*, of Nuttall, becomes a variety of *C. Douglasii*; *C. berberifolia* is a variety of *C. Crus-Galli*; and *C. elliptica* is reduced to a variety of *C. flava*. It is to be hoped that these plates will direct attention anew to the value of our native Thorns as ornamental plants. The plates are all so excellent that it is impossible to select any one of them for particular comment, but every botanist must at once appreciate the aid which the illustration of *C. punctata* will render in elucidating a handsome species which has been too long overlooked or neglected.

The Juneberry, or Service-berry, which is now coming into cultivation, appears as *Amelanchier Canadensis*, var. *obovalis*, instead of as var. *oblongifolia*, as heretofore. Another variety of *A. Canadensis* is recognized in var. *spicata*, which is the *A. ovalis* of botanists (but not of recent horticulturists). This variety is characterized by "broader obovate, sometimes suborbicular, leaves," and "is common in the northern states." The western Service-berry is kept distinct from the eastern species as *A. alnifolia*.

Aside from the inestimable value of the running text and the plates, the foot-notes abound in historical matter, and those concerning the cultivated Plums, Cherries, Apricots, Peaches and Apples are among the best concise statements concerning the origins and botanical features of these fruits which have been published.

This volume of the *Silva* is appropriately dedicated "to Horatio Hollis Hunnewell, a true lover of trees and a wise and generous patron of the arts and sciences."

Cornell University.

L. H. Bailey.

Notes.

One hundred and twenty years ago the ground upon which stands the Lutheran church at Mannheim, Pennsylvania, was donated to the congregation by Baron Henry William Seigel, who had founded the town, upon consideration of the annual payment of one red rose. This pretty rent was twice demanded and paid before the death of the baron.

Our native Spiked Loosestrife (*Lythrum Salicaria*) is a most effective plant for the borders of artificial water or in damp places, where its purple-lilac flowers, borne on spikes from four to six feet high, show well against masses of foliage. It is one of those sturdy plants which will take care of themselves when once established, and it has the advantage of keeping in flower for a long time.

Americans are often called an unsentimental people, but, in fact, their sentimentality constantly reveals itself in ways which must seem surprising to foreigners. For example, not content with making a simple exhibit of their famous Blue-grass at the Chicago Exhibition, the Kentucky committee proposes to collect the sods from historic spots, as from the home of Henry Clay, the birthplace of Lincoln, and the battle-field of Perryville.

The Edelweiss, one of the most beautiful and quaint of mountain flowers, is doomed to extinction, says the *Cornhill Magazine*, because tourists in Switzerland consider themselves bound by fashion to wear a couple of dried specimens in their hats and send them home gummed to a card. We are glad that the government in one or two of the cantons has interfered to save the persecuted plant, and has made it a finable offense to pluck its flowers.

In Japan, writes Mr. Lafcadio Hearn, "stones are valued for their beauty, and large stones, selected for their shape, may have an æsthetic worth of hundreds of dollars. And

large stones form the skeleton or frame-work in the design of old Japanese gardens. Not only is every stone chosen with a view to its particular expressiveness of form, but every stone in the garden or about the premises has its separate and individual name, indicating its purpose or its decorative duty."

The weekly exhibition at Horticultural Hall, in Boston, on Saturday, was not large, but the fruits and vegetables displayed were unusually fine. The spikes of double Hollyhocks shown by J. S. Fay and N. T. Kidder were of the best quality, and some of the newer Sweet Peas were very interesting, on account of their delicate colors. The herbaceous plants sent by Rea Brothers and the wild flowers collected by Mrs. P. D. Richards added much to the interest of the exhibition.

Some of the Bush Honeysuckles make a beautiful display at this season with their bright-colored fruit. The old Tartarean Honeysuckle is one of the very best of shrubs for the north, as it will endure the severest winters. It has an admirable habit, flowers abundantly, and its different varieties bear crimson or yellow berries, which have now ripened to their richest coloring. *Lonicera Morowii*, from Japan, is fairly loaded with bright red fruit clustered among leaves of light green, while the branches of *L. Ruprechtiana* bend under the weight of its berries of the same color, although covered with a slight bloom. This last shrub comes from Manchuria. The beautiful fruit of all these Honeysuckles, coming at a season when flowers in the shrubbery are rare, gives them especial value.

The preference which English buyers show for foreign-grown apples is not very encouraging for this industry in England. The growers wish to have their apples protected by imposing an import duty upon the foreign-grown product. One journal answers this by saying that it would be hard to force housekeepers to make their puddings with apples which are high-priced but of inferior quality. At a recent banquet of the British Fruit Growers the proposition was made that all apples exposed for sale be marked "Foreign" or "English." This proposition was enthusiastically received. In this manner English protectionists will not be obliged to buy apples which have the misfortune of having been grown under a foreign sun. In spite of English opposition to foreign-grown fruit the papers continue to announce the arrival of successive shipments, all of which sell rapidly. It is estimated that about 240,000 bushels arrived during the spring months, all coming from Tasmania. Six weeks are required for transportation.

In his description of a trip down the Danube, Mr. Frank Millet says, in the July number of *Harper's Magazine*, that at Hirsova, near the Russo-Bulgarian frontier, the river "divides into a number of branches which enclose and intersect with sinuous windings a great irregular marsh twelve or fifteen miles in width. The shortest of the sluggish branches of the river skirts the eastern limits of the Roumanian plain, and paddling into this narrow channel we found ourselves in a short half-hour in a region quite unlike any we had yet seen. Both banks are low and covered with tall Reeds alternating with Willow-patches. The only habitations are little fishing-stations, and these are miles apart. The fishermen's dwellings are hovels of the rudest kind, built of mud, thatched with reeds, and surrounded by fences of the same material. The botanist whose duty it was to gather drift-wood brought back from his rambles a great bouquet of wild flowers—*Melilot*, *Loosestrife*, *Convolvulus*, *Blue Veronica*, *Chicory*, *Tamarisk*, *Snapdragon* and many others."

A correspondent, in speaking of our commendation of the Prairie Rose (*Rosa setigera*), writes that he has examined all the nursery catalogues he can find, and no one seems to have this plant on sale. We see no reason why this plant, which is one of the handsomest of all single Roses, should be neglected by commercial growers, especially since it has the advantage of flowering as late as almost any other single-flowered Rose except the *R. foliolosa* from Texas. We recently saw it in a southern city trained over the veranda of a cottage, where it made a more beautiful display than any of the double-flowered Roses growing on the neighboring houses. This is one good way to use the Prairie Rose, although it probably looks best when planted at the top of a bank and is allowed to send down its long, vigorous and graceful shoots irregularly to the bottom. It is a good subject to plant as a single specimen on the margin of a lawn. If it is set in good soil and with sufficient room its arching stems will form a mass of foliage ten or twelve feet in diameter. It has been in bloom now for three weeks, and its large clusters of pink flowers show admirably against the pale blue-green foliage.

Mr. James MacPherson writes to *The Country Gentleman* of some fine trees at the old Moon Nursery, at Morrisville, Pennsylvania, which was established about fifty years ago. A Pin Oak, which was planted some forty years ago by the father of the present Mr. Samuel Moon, now girths eight feet and ten inches four feet from the ground. A Bur Oak at the same height, and thirty years old, has a circumference of seven feet, and the Willow Oaks show as strong a growth. A Purple Beech, thirty-five years old, girths eight feet and nine inches three feet above the ground, and another specimen, only twenty-five years old, is forty feet high and six feet in girth. The Japanese Red Bud seems to have reached its maximum development here, one specimen being fourteen feet high and twenty-one feet in diameter, while *Exochorda grandiflora* is about the same size. These figures show that it ought not to be a discouraging thing to plant trees, and, as Mr. MacPherson well remarks, a young man who begins to plant when he gets married may have trees to be proud of before his children leave him.

The Sierra Club, recently incorporated in San Francisco, is a corporation formed to explore, enjoy and render accessible the mountain-regions of the Pacific coast; to publish authentic information concerning them; to enlist the support and co-operation of the people and the Government in preserving the forests and other natural features of the Sierra Nevada Mountains; to take, acquire, purchase, hold, sell and convey real and personal property, and to mortgage or pledge the same for the purpose of securing any indebtedness which the corporation may incur; to make contracts and transact other business pertaining to the corporation and the management of its property. John Muir is President, and Warren Olney is the First Vice-President of the club. Applications for membership may be addressed to the Secretary, William D. Armes, University of California, Berkeley, California, the admission fee being \$5.00, while the annual dues, except for undergraduates of colleges and members residing beyond certain counties in the neighborhood of San Francisco (which is placed at \$1.00), is \$5.00.

In an article entitled "Pestiferous Plants," in the *Popular Science Monthly*, Professor B. D. Halsted says: "The fact is patent that weeds are everywhere present, and the best means ought to be taken to resist their greater prevalence. In this warfare against them there is no weapon equal to a thorough knowledge of the enemy—that is, an understanding of their nature, their appearance in all stages of growth, their methods of propagation and dissemination of the seeds. This knowledge is much more highly appreciated in Europe than here. In Germany, for example, they have wall-maps upon which the leading weeds are represented. Hung as these are upon the school-room walls, a child, simply from daily seeing these life-like colored drawings of the various pests, will learn their appearance and names. Some such method of instruction is needed in this country, by which the children who are soon to be our farmers and gardeners may become familiar with the troublesome weeds even in advance of their advent, that the proper means may be taken at once for meeting and destroying them. Editors of agricultural papers and professors in agricultural colleges yearly receive many letters asking for the simplest kind of information concerning many common weeds, thus showing the general lack of knowledge upon this important subject. To put a map of a dozen of the most destructive weeds upon the walls of every country school-house in the United States is a great undertaking; but, if it were done, the next and succeeding generations of farmers would be the better able to carry on the work of extermination. There are a large number of farmers' clubs throughout the country, and a great deal might be done by hanging a weed-chart upon the walls of these halls, where farmers gather from time to time for mutual improvement and a better understanding of the ways and means of a more profitable agriculture. Weeds have been neglected in more ways than one, and just so far as they are overlooked and left to themselves the greater will be the curse. As we look over the premium-lists of our thousands of county and state fairs we seldom see a prize offered for the best collection of weeds. It seems incompatible with our fitness of things to have a good collection of anything that is bad; and yet the fact remains that there is no class of plants about which an increase of knowledge is more imperative than these same ugly weeds. A few dollars expended in awards by each fair association would bring together lists of plant pests, the exhibition of which would not only surprise but greatly instruct those who see them. It is not less important for the farmers of any district to know of the arrival of a new weed than of the advent of a new fruit or grain."

Umbellularia.

OF the Laurel family some fifty genera and nine hundred species are distinguished. These are chiefly tropical, and are American, Asiatic, Australian and Polynesian. A few species are found outside the tropics in southern Europe, the Canary Islands, south Africa, New Zealand, and North and South America. The species are mostly woody, and are distinguished by minutely punctate alternate simple leaves with entire margins. The flowers, which are always minute and are perfect or dioecious, are usually arranged in umbellate clusters or cymes, the perianth, which is generally white or yellow, being composed of four or six sepals; there are no petals, numerous stamens in three or four rows, the anthers opening by one or two uplifted valves, and a single style and stigma. The fruit is fleshy and berry-like, or rarely drupaceous or sometimes dry, and is always indehiscent. The plants of this family secrete in the bark and in the glands of the leaves and flowers a pungent volatile oil which has stimulating or sedative properties. To it is due their chief value to man, although many of the species produce timber of great strength and value, and *Persea gratissima*, a native of South America, yields a large, succulent fruit—the avarcado or alligator pear—for which this tree is cultivated in all tropical countries. To this family belong the Cinnamon-trees cultivated in the tropics for their fragrant hot, sugary bark, and the Camphor-tree, a native of China and Japan, cultivated in the far east for the colorless volatile fragrant acrid oil, the camphor of commerce, which is distilled from the wood. To this family belongs, too, the Laurel of southern Europe (*Laurus nobilis*), one of the plants called *Daphne* by the ancients, the reward of the victor, and still the best ornament of the gardens of southern Europe. A tree of the Laurel family (*Nectandra Rodiæri*), a native of Demarara, produces greenheart, one

of the most valuable tropical woods known to the cabinet-maker; the Brazilian *Licaria Guayanensis* yields pepper-wood, so called from the pungent character of the dust made in working it; and *Persea Indica*, the so-called Madeira mahogany of commerce.

With the exception of Japan, temperate North America is probably richer in species of Lauraceæ than other extra-tropical regions. In the eastern United States five genera are represented by seven species. The best known of these is the Sassafras, one of the most beautiful trees of our eastern forests, which it inhabits from New England to Texas. No tree is so often mentioned as the Sassafras in the annals of the early travelers in America, who imagined it one of those spice trees of the east which fired the imagination of Europe in the fifteenth and sixteenth centuries; and many expeditions were fitted out for the purpose of gathering the bark and roots of this tree. The family is represented, too, in eastern America, by the Red Bay (*Persea Carolinensis*), a handsome, small tree of the maritime region of the southern states, well known for its beautiful, bright red heart-wood; by the Lance-wood (*Nectandra Willdenoviana*), a tropical American species found also on the coast and islands of southern Florida; by the familiar Spice Bushes (*Lindera* and *Litsea*), and by the curious leafless parasitic climbing *Cassyta* of southern Florida. In the forests of Pacific North America, Lauraceæ is represented by a single species, *Umbellularia Californica*, the noblest member of the family in North America, and one of the most beautiful evergreen trees of the north temperate zone.

The genus *Umbellularia*, established by Nuttall and still only represented by the California Laurel, is distinguished by its perfect flowers, borne in stalked terminal and ultimately axillary umbels, which are included before expansion in involucre composed of four broad deciduous bracts; by a six-parted deciduous calyx, nine stamens inserted in three rows, those of the inner row being furnished with a fleshy gland on each side of the base, alternating with three staminodia, four-celled anthers, a dilated stigma, and a dark purple sub-globose drupe an inch in length, and surrounded at the base by the thickened remnants of the calyx. The leaves, which are lanceolate-oblong, are sometimes four inches in length, and are dark yellow-green and very lustrous; they are delightfully fragrant, although exceedingly acrid, and give off when bruised a pungent effluvia which excites sneezing. The California Laurel has been referred by botanists to a number of different genera, and to the people of California it is known also as Mountain Laurel, Spice-tree, Cajiput, California Olive and California Bay-tree.

Umbellularia is common in all the coast-region from southern Oregon to the southern borders of California, and it is not rare on the western slopes of the Sierra Nevada Mountains. In the valleys of Oregon and northern California, in rich soil and in the neighborhood of streams, the California Laurel is most abundant and grows to its greatest size, rising sometimes to the height of a hundred feet and making tall stout stems five or six feet in diameter. At the north it sometimes forms forests, either growing by itself or in company with the great Oregon Maple (*Acer macrophyllum*). In central and southern California, especially when it grows beyond the coast-region, the California Laurel is a smaller and often a bushy tree, which only in old age assumes the spreading habit and forms the graceful head peculiar to fine specimens of this species.

The value of the California Laurel as an ornamental tree is very great; the forests of Pacific North America do not contain another tree better suited to adorn the parks and gardens of that state, and certainly the most beautiful gardens in California are those in which single specimens or groups of this tree were left when the indigenous growth was originally cleared away. A view made of such a garden by our obliging correspondent, Mr. F. Gallaher, of San Francisco, appears in the illustration on page 355 of this issue, in which may be seen a plant of *Umbellularia* with

the habit which it assumes when it has grown in the open ground and the development of the lower branches has not been interfered with, and which is quite different from the stately, long massive-stemmed habit it assumes in the dense forests of southern Oregon.

As a timber-tree *Umbellularia* is extremely valuable. No other Pacific-coast tree produces such valuable timber for the cabinet-maker and joiner. The wood is rich light brown, heavy, hard, very strong, and close-grained, the satiny surface, often marked by contorted and twisted grain, being susceptible of receiving a beautiful polish. It has been much used in California for furniture and the interior finish of dwellings, and in Oregon for the cross-trees, cleats, bits and jaws of ships and boats.

It would be interesting to know if this tree, which was transported many years ago into the gardens of Europe, has succeeded in establishing itself anywhere beyond the region of its home. It might be expected to flourish in southern Europe, and to surpass the true Laurel there in size and beauty; in some parts of India and Australia, and in southern Japan, we should expect also to find *Umbellularia* growing into a stately and beautiful tree, although it is in California, no doubt, that it is destined to play its most important part as an ornamental and as a timber tree.

A CRITICAL examination of several parts of the Central Park in this city shows that the ten thousand trees which the managers claim that they have removed during the last three years are not missed, and that their removal has left no unsightly gaps. Indeed, the park is still so overcrowded with trees that it is difficult to realize that its plantations have ever been thinned. The park, as a work of art, is suffering because surplus trees are filling up the open glades and recesses of turf along the drives, and are gradually cutting off all the vistas which gave the landscape variety, mystery and interest. For this reason the park is becoming, every year, more and more of a wood, and less of a park, as it was originally designed. But more important than the loss of design, which can always be restored in a comparatively short time, is the danger of ultimate ruin to all the trees in the park by overcrowding. In every direction short-lived, misshapen, scrubby or half-dead trees are using up the light and air and soil needed for better specimens which would last for a century if they were allowed the chance to grow. It is probably not an exaggeration to say that the park and its plantations would be immensely improved by the immediate removal of one-half of the total number of trees now growing in it, and that six months after they had been cut, not one person in a hundred thousand visiting the park would miss them or realize that the axe had been at work.

For years the trees in the park have been neglected, and they are now beginning to show the effects of this neglect. They were not properly thinned when they should have been, because the commissioners of that time declared that they feared to face the popular outcry against cutting a tree. But in these last years the people of this city have learned a great deal about their park and its requirements; they realize its value now as they have never realized it before; they know more about trees and their needs than they did a generation ago, and the commissioners may be sure that they will be supported in any well-considered and carefully studied scheme for improving the park plantations. They should not allow another winter to pass without beginning a systematic thinning of the trees under their charge, for now that they have become so large and overcrowded, they suffer more serious injury in one year than was possible in ten years while they were still small.

WE have heard, from what seems to be a trustworthy source, that the Yosemite Commission has just agreed to pay a contractor \$3,000 to "underbrush the valley." Precisely what this phrase means we do not know, but in view of what has happened when zealous choppers have

turned themselves loose with axes in that beautiful spot, the news is enough to excite apprehension. Every one who has visited the Yosemite recognizes the singular charm which the beautiful growth of shrubs and small trees gives to it. The persons who were at one time in charge of the valley certainly did not appreciate the value of this low growth and its luxuriant foliage. It is just possible that there is some one now in command who can be trusted to spend money for the "improvement" of the valley in such a way that it will not add to the disfigurement which the place has already suffered, but certainly this is a matter which ought to be discussed and explained. This valley belongs of right to the people of the United States. Its unique beauty and grandeur should be theirs to enjoy, and for their children to enjoy forever. It would be a disgrace to civilization, as well as an outrage upon the plainest justice, if any unskilled hand is allowed to be lifted up against the trees and shrubs of the valley. What the people have a right to demand in such cases is the widest publicity. No one will question that for any alleged improvement of the Yosemite Valley there should be a fixed plan, and that this plan should be published; that no haphazard work should be undertaken; that not a tree should be cut, and not a lane laid out without minute directions and without every needed restriction and protection against possible injury to the beauty of the place.

Let the people know just what is going to be done in the Yosemite Valley, why it is to be done, and who is to do it.

THE forty-first volume of *The Garden* is dedicated to our excellent correspondent, Max Leichtlin, of Baden-Baden. In the dedicatory remarks we learn that he was born at Karlsruhe, in Baden, on the 20th of October, 1831. When fifteen years old he became an apprenticed gardener, and afterward held gardening situations at Frankfort, Bolweille and Ghent. Some years of his life were then spent in traveling, and in 1856 he returned to Europe from South America; then, after spending a few months in Dublin, he served for two years in Van Houtte's nursery, in Ghent, which at that time was considered one of the best schools of horticulture in Europe. Leaving Ghent he engaged in the business of paper manufacturing with his two brothers, and for sixteen years devoted himself exclusively to this occupation. Then, having amassed a considerable fortune, he retired to Baden-Baden and founded the private botanical garden which has since made the name of Max Leichtlin a household word wherever hardy plants are grown. No man of our time has introduced so many first-rate hardy plants into cultivation, and no one has been more successful in cultivating and propagating them. Bulbous plants especially have interested Max Leichtlin, and his collection of Lilies at one time was the richest in existence. Afterward he devoted himself to Irises, and has introduced many interesting species. As a raiser and hybridizer he has achieved great success with the Nerines and Aubrietias, some of the best varieties of these handsome genera being due to his patient skill and perseverance. It is to him that gardens are indebted for *Jankæa Heldreichi*, *Ostrowskia magnifica*, the largest known Bellflower, *Meconopsis aculeata*, *Tellima parviflora*, and a host of other plants, including many Lilies, Tulips, Alliums and Irises, especially of the bulbous and *Oncocyclus* sections. Max Leichtlin is as generous as he is successful in gardening, and his greatest happiness is found in sharing his treasures with his friends and correspondents, who are always being placed under a debt of gratitude to him, not always easy to repay in kind, as no plant interests him unless it is new or extraordinarily rare, or so difficult to cultivate that everybody else has given it up as hopeless.

The landscape, forever consoling and kind,
Pours her wine and her oil on the smarts of the mind.

—Lowell.

Cultivating the Almond in California.

THE estimation in which the almond is held in America is seen from the fact that nearly six million pounds of these nuts were imported in the fiscal year ending June 30th, 1890. They were valued, too, at \$813,000, or considerably more than all other imported nuts put together, and this, not because they are the cheapest, for they are the most expensive of imported nuts. There are no reliable statistics of the home production, but the area suited for almond cultivation is confined to a few spots distributed throughout the whole length of California, and it is doubtful if there is enough of it, all told, to supply the American market. In the last number of the *Popular Science Monthly* Mr. Henry J. Philpott gives a description of the processes by which this favorite nut is produced and made ready for holiday tables, from which we condense the following statements:

The trees are all budded or grafted, for although a seedling Almond may be an improvement on the parent tree, it is apt to be worthless, and may be deadly poison. This inclination to sport is seen even in grafted trees, for in Mr. Philpott's orchard, in which the cions were all taken from the most prolific bearers of the best nuts among tested trees, some of them never bear at all, others bear worthless nuts, one yields a nearly perfect peach-pit enclosed in a nearly perfect almond-drupe. The variety known as the California Paper Shell, originated near Mr. Philpott's ranch, is very distinct, although a purely accidental seedling. Its good size, plump kernel, thin shell, sweet flavor and agreeable appearance enable it to command two or three cents more a pound than any other nuts in the market. It is truest of all to the type and most distinct in the form of the tree. Some growers claim that it is less prolific than many other varieties, but others say that it is the most hardy and most prolific as well as the most salable almond grown, and it is predicted that it will drive the foreign nuts out of the market.

The Almond-tree resembles in size and shape, as well as in smoothness and color of the bark, an unpruned Apple-tree, while it is the image of a Peach-tree in foliage and green fruit. The leaf is so exactly like that of a Peach, to which it is nearly related, that a casual visitor can scarcely distinguish them. The same is true of the fruit in a green state, which is a peach in taste and smell. The Almond is commonly grafted on Peach-stock, and an orchard of these trees in bloom is a thing of beauty.

The cultivation of the Almond is very easy. The orchard is plowed and harrowed once or twice a year, and then the weeds are kept down in the easiest manner possible, but the tree is never pruned, and the fruit is never thinned, both of which operations cause great expense in the cultivation of other orchard fruits, while so far it is infested with no parasites, and the grower is not at the expense of buying and applying insecticides or fungicides. First to bloom in the spring, the Almond is the last to mature in the autumn. All summer long the fruit hangs, the image of a green peach, and after the first few weeks never increasing or changing in appearance. Late in August the seam, which is rather deeper than in most peaches, will open in a few of the earliest, and then the growers are anxious to know whether the almonds will open and remain open, or whether the drupe will remain closed, or will open partially and then close tight, for the whole profit of the crop may depend on the behavior of the fruit in this respect. It may cost half of what the crop is worth to pick and husk it.

The nuts are knocked off of the tree with long poles, and if they are well open they are allowed to drop on the bare ground and are husked as they are picked up. Those which do not open are husked with the fingers. The variety mentioned above is one of the freest, and its drupe often falls off spontaneously and leaves the naked nut hanging to the tree. But the nut so freed from the drupe clings tightest of all to the stem and is often hard to knock down without injury to the branches. In the best of seasons a large part of the crop is so badly opened that a canvas is spread under the tree for the nuts to fall on. When all are knocked down the canvas is rolled up and carried to a place where there is a simple table of boards. One picker rubs the nuts to loosen the drupes, and the others husk. The rubber is practically two old-fashioned washboards which slide over each other. The machine is a flat-bottomed trough, six or eight feet long, and open at one end, across the bottom of which pieces of lath are tacked an

inch apart. The nuts are scooped in, a few pounds at a time, and a shorter board, also ribbed crosswise with lath and handled like a flat-iron, is rubbed over them, loosening their husks and pushing them toward the open end of the trough, where they fall into a box to be husked. In larger orchards more complicated machinery is operated by horse or steam power, but the drupes and nuts are still separated by hand. The drupes are generally only loosened by the machine; few of them are rubbed completely off, because, if force enough were employed to remove the drupe, it would break the shell; therefore, in many orchards this year, the only way to market the almond was to crack it with the drupe on and sell the kernel.

Picking and husking almonds costs from \$50 to \$100 a ton, after which the nuts are sent to be dried and bleached with the fumes of sulphur, a process which requires care and experience. If this is done well and the nuts come out bright and evenly bleached the grower is satisfied, for he knows that it is the color which sells his almonds. It is claimed that fruit, such as apricots and apples, which is sulphured is poison, and yet unbleached fruit will not bring living prices. It is not probable, however, that sulphuring, as it is conducted, is of any real injury even to evaporated fruit, but in the case of the almond it is only the shells that are colored. As a rule, the harder the shell the whiter the almond will bleach, although this new Paper Shell of California will bleach the whitest of all.

When cured for market, the nuts are stored and shipped like barley, in coarse gunny-sacks, and although a single sack costs but seven or ten cents, the whole expense is a burden on California producers to the amount of \$2,000,000. Where grain has to be handled from five to ten times before it reaches the consumer, and all grain is shipped from the Pacific ports in this manner, the sack is a still more expensive crudity, and the grain-grower loses by it ten per cent. of his gross proceeds. But the burden on the Almond-grower is trifling, one per cent. perhaps of the gross product, and the sack is altogether an advantage, for it saves the delicate shell and furnishes a place for the brand of the orchardist, who is proud of his product and wishes to work up a reputation for it, and it also gives an opportunity for naming the variety contained in each sack.

The practical question confronting each prospective orchardist is, How soon will trees come into bearing and pay expenses and interest on the investment? Some old men who have tried it conclude that too much planting for posterity is mistaken kindness, for which posterity, lying in the shade, kicking up its heels and letting its faculties rust for want of some planting to do, returns no thanks. But the Almond is an early bearer. At four years, from seed, Mr. Philpott's orchard yielded \$80 per acre gross, say \$60 net. This year, at six years old, with prices considerably below the average, the proceeds will be \$125 an acre. Few orchards have yielded so much per tree of the same size, but these trees are so wide apart that there are only half the usual number to the acre. While the trees are small, this tells against the yield per acre. In a general way, it may be said that an Almond-orchard yields as quick a return as a herd of beef-steers, and at the same time the planter does not lose the use of his land. He plants other crops between the rows, but, of course, no ordinary annual crop will yield a profitable return from the price he must pay for land known to be adapted to almonds. The almond, most precious by weight of all orchard-products, involves less labor, care, anxiety, expense and skill than any other, excepting, perhaps, the Prune. In recent years it has never yielded the fabulous returns realized by the growers of some other fruit or nut. It never yields, as an Orange-orchard has, a competence for life in a single year from ten acres. Its reasonable expectations are about \$100 net per acre.

Wild Flowers in Italy.

ABOUT the 20th of May the Italian summer overtakes us on the hill-top where this city sits. We do not then, however, experience its full power, the still, steady fervor which July has in store, but merely the soft freshness of a perfect New England June, in response to which millions of Roses break bud and send gentle waves of perfume all through the ancient city. Roses are there everywhere. Enter a shop in the busiest street, and a great Maréchal Niel nods at you through the open window at the farther end. Pause before the open door of a frowning fourteenth-century palace, and across its paved court-yard you see a tangle of cream and crimson blossom. For there is here none of the prim formality of an English garden of "standards"—a collection of walking-sticks supporting a half dozen overcultivated flowers.

These bushes and vines were freely trimmed by their owner last autumn, no doubt, but it was in self-defense he did it; in protection of his right of way along his own garden-paths; and in spring they show a wealth of healthy green, and blossoms which rival in number, size and perfection any prize collection at an English flower-show. It is all due, of course, to what Mr. Cable's engaging heroine called "doze climéd," and if climate can do all this for us within city walls, what need to wander restlessly abroad, exploring country roads and lanes? Yet such strolls when the afternoon shadows have grown long, and the afternoon breeze comes breathing up over the piny hills and poppied fields from the unseen sea, are very wholesome both for mind and body, especially the former; and out in the open country we find a most rich and varied vegetable life; old friends whose welcome is sweet, new faces with whom one longs to make closer acquaintance.

But, alas! you will, to carry on the metaphor, find it next to impossible to procure a proper introduction to these rustic beauties. Their very names, for the most part, will remain unknown. I do not think there is such a thing as a handy botany of this district, and to the average Italian of the lower class wild flowers are objects which it would be beneath his dignity to observe too closely. Show him an Iris, and ask him how it calls itself in Italian. Giovanni will cock his head on one side, ponder sagely, and, four chances out of five, pronounce it a rose. "Angiolina," I asked the other day, as she and I were passing a clump of the great, pale lemon-colored Dandelions of the region, "what is the Italian name of those flowers?" She looked at me bewildered. "Signorina, I haven't the remotest idea." Not to be discouraged, I pursued my catechism. "Do they ever grow any larger than those?" They were full two inches in diameter. "Oh, yes, signorina," she replied briskly, "much larger; and then," triumphantly, "we call them Sunflowers."

When one is thwarted in this fashion in the pursuit of knowledge it is better at once to renounce the vain thought of imparting useful information, and only repeat to those who may be disposed to give them a practical trial some of the suggestions which this country-side calls up.

The field at your left is dyed deep crimson with the splendid blossoms of the Sainfoin, or dark red Trefoil, long a favorite in France, and sown in greater quantities every year both here and in England, where enthusiastic praise is bestowed on its virtues as fodder, whether green or dry. I think it might prove of practical value to our serious farmers, but let the amateur, at all events, try a belt of this Clover on the dubious boundary between his lawn and mowing-field, sowing thickly in early spring. Let him be careful to get the true crimson variety, and not that which flowers rose-pink, and after watching its rich green growth and the opening of its close-set sturdy heads, I will predict that, if he rejects the Sainfoin as a crop, he will keep it up as an ornament.

Now lean over the hedge, and continue the line of your meditations. The lane you are following winds steeply up a hillside, and between its boundary hedge and the level of the field beneath there is an almost perpendicular drop of eight or nine feet, and on this abrupt slope a dozen sorts of grain and tall blossoming grasses are nodding their heads in enticing confusion, completely veiling it with a covering delightful to the eye of the casual observer. Is not this a suggestion for that terrace front beyond the garden, to which the hose will not reach and which always turns brown so early in the summer? You may not succeed quite so well in your combination as nature does after a century or two of self-sowing; but an average seed-chest has resources which are not to be despised, and with a little patience these may be most effectively supplemented by our beautiful wild grasses, and the bank thus laid down will be an inexhaustible resource for your flower-jars. I remember certain narrow, deep-cut, Beech-shaded lanes in Surrey where native grasses were said to have been systematically sown some years before, with the most beautiful result at the time I wandered there.

And here I would like to put in a plea for the formation amid so many Societies for Rural Improvement, of one for the Preservation of Lanes. Broad ways, between unbroken lines of evenly spaced Maples or Elms, and trim bands of close-cut turf are pleasant and desirable in their place, and their place is a large one; but there should be room as well for the narrow winding lane where the horses walk rather than trot, and the air always bears some woodland scent—the spicy fullness of the Pines, the delicate sweetness of the wild Grape-bloom, or the pungency of the Barberry; where the Birches leave room for Sumac and Blackberry vines, and the Asters and Golden-rod blow no less bravely because Columbine and Violet have preceded them.

I would have my society do something also for the bare "cuttings" and dreary borders left along new roads, assisting nature in her slow business of clothing them gracefully. Its province, and that of the road commissioners, should be clearly defined and separated, and it should be composed of members all ready to take suggestions from nature's methods, and to try perpetual experiments in the introduction of the wayside beauties of other lands; content to have a dozen fail if one may but succeed. Let us see what can be done with some of the wild Roses of Switzerland, above all that tall, red-stemmed bush which bears flowers of a deep Jacqueminot crimson, among its blue-green leaves; or, to come back to this Tuscan country, with the pure white Sweet-brier, which grows luxuriantly hereabout by the side of the common pale pink variety. And one or two of the sweet-scented Honey-suckles which gush over these hedge-rows, intertwined with a Clematis which I have seen rioting at home, could they not be coaxed to endure the New England climate? Certainly there are places in America where the Rock Rose might be enticed into springing, as it does here, from the face of the most incurably barren cliff, and where the yellow Tulip and lavender Iris might follow the line of some meadow causeway. Let us have, too, the hardier Thorns, both for the sake of their spring blossoms and their winter haws, and there is a species of ground Holly, with a showy scarlet fruit, nearly as large as a small cherry, which is warranted to render any spot inaccessible to marauders, and might be found useful as well as ornamental. There is also the pale, primrose-colored Dandelion, of which I have spoken before. It is a gorgeous flower, but I cannot give it a first-rate moral character. It is undoubtedly a sybarite, and rather than lead an honest independent roadside existence, it clings to the luxuriant life of the market-garden, and prefers to hang on to the skirts of society there, even at the perpetual risk of being ignominiously expelled.

A little later, when summer is at its fiercest here in Tuscany, our lanes will blaze with the most superb Thistles, high and low, big blossoms and small, single flowers and clustering heads, bright blue and royal purple, silver-white and tawny orange; but the Thistles, too, shall be left undisturbed, and, indeed, our Asters and Golden-rod give much the same range of blossom-color, though their foliage cannot be compared with the sculpturesque and highly decorative leaves of the Thistle. It occurs to me, however, that by insisting too much on the æsthetical properties of the Thistle I may weaken in the eyes of the gardener at home the force of my practical suggestions, so I will close these desultory remarks before compromising myself further.

Siena, Italy.

Louise Dodge.

A Bed of Hardy Perennials.

"THE well-furnished garden should be gay with blossom throughout every month of the growing season."

This axiom being indisputable, we have suddenly awakened to the conviction that our garden is deficient in midsummer attractions. A few Roses are blooming for the second time, notably Madame Alfred Carrière, which is making a display that would be very creditable even in early June, and that is worthy of all praise in this sultry July weather, and Madame Georges Bruant, which is almost as lavish of flowers as its more graceful neighbor.

The long borders behind the house are very gay with Geraniums and sweet with Heliotrope and old-fashioned annuals, and in the shrubberies are many tall, cool-looking Hollyhocks, pink and white and mauve, with double and single flowers, with groups of various Hypericums, whose yellow flowers are most acceptable and cheerful. But with all the lavish beauty of Trumpet-creepers, beloved of humming-birds, and Clematis of many kinds, we feel that there is something lacking, and are conscious that we have sadly neglected two very valuable classes of midsummer flowers. These are the herbaceous perennials and the newer annuals.

The truth is that our devotion to trees and shrubs has been so faithful and absorbing that we have had no time to spare for the humbler denizens of a "perfect pleasaunce." Now, however, that we are awakened to a sense of our deficiencies we have turned our attention to our nearest neighbors in marsh and meadow, and are trying to induce some brilliant blossoms near at hand to be content with a change of residence from field to garden-border. We have taken up large clumps of *Asclepias tuberosa* in full bloom and transferred them to our shrubberies. Any one who has tried to move these handsome plants on a sultry day in July will doubtless remember the undertaking. Almost inconceivably long and tenacious are the roots, which they thrust into the rocky soil. It was

almost an impossible task to carry out my instructions that the plants be removed with earth about them and with unbroken roots. Of five clumps planted a fortnight ago only one is in a flourishing condition at this time.

Much better fortune has attended a large bed of late-blooming perennials planted a few days ago. These came from Mr. John Saul, of Washington, a careful grower of everything a garden ought to possess.

Our summer hammock swings from two large Oak-trees on a little eminence which commands a wide view of field and wood and mountain-range on one side, the grove, with its winding roads and shady glimpses, on the other, and a smooth expanse of shrubbery-bordered lawn just in front. At the extremity of this little lawn is the new bed, already interesting with many blooming plants. These were carefully packed and sent with balls of earth around the roots, and cool damp moss to refresh them during the journey. They were at once transferred on a cloudy afternoon to their permanent resting-place.

This morning the tall-blooming Phloxes are as fresh as Phloxes can be, and seem to be gazing with wide-eyed approval at their new surroundings. Unfortunately there are many undesirable colors among the flowers of Phloxes, and it is very difficult to group them effectively. Among our scarlet Geraniums at the back of the house, the magenta and solferino of some ancient Phloxes that will not die are very incongruous, and I frequently take myself to task because I lack spirit to exterminate them. But they are relics of the past, and were familiar to my childhood, and so, from year to year, they are allowed to injure the color-effect of our Geranium-bed. The new Phloxes just received are in softer shades; some are pearly white and others a faint pink with darker eyes. All these are grouped together, apart from other plants, and are best so, belonging as they do to such a very exclusive family.

Blighted Leaves of Pelargoniums.

The Blackberry Lily, *Pardanthus Sinensis*, which was in bud when it came, has opened a few handsome blossoms, and the Campanulas and *Platycodons* are beginning to flower afresh. A very few of the new plants are drooping. We water them in the twilight and shade a little during the day. The weather is warm and unfavorably dry, yet we have every reason to rejoice in the success of our experiment.

The new Yarrow, or *Achillea*, called the Pearl, is blooming profusely, and does not seem to recognize any difference between the nursery in Washington and the garden at Rose Brake.

Rudbeckias are charmingly bright and saucy, and a *Sedum* labeled *Sedum Silskanum*, which is new to me, is showing a few yellow star-shaped blossoms.

This bed is very conspicuous from the hammock, and will, no doubt, be a constant source of pleasure as the plants increase in beauty day by day.

Cultural Department.

Blight of Variegated Pelargoniums.

GARDENERS are getting shy of some of the variegated plants. Last evening, while talking with a large grower of foliage plants, it was learned that he had discarded some of the plantain Lilies, and particularly the *Funkia undulata*, var. *variegata*, because they blight so badly. Such plants will do well for a part of the season, and as soon as the more trying days of midsummer come, they become unsightly and worthless.

Attention at this time is called to a similar behavior of the variegated Pelargoniums. Some of these are very showy border-plants, so long as they remain in good health. Under the most favorable circumstances, plants of these variegated

sorts may retain their handsome foliage, but as a rule the leaves become blotched and brown. While there is no doubt that variegated plants are abnormal, in so far as their chlorophyll or "leaf-green" is reduced, and, therefore, less able to

Blighted Leaves of Pelargoniums.

compete with ordinary plants in the making of food out of the crude materials of the soil and air, it is likewise an observed fact that such plants fall more easily a prey to the attacks of parasitic fungi. In short, a variegated plant is inherently weak, and, therefore, less able to resist the enemies that are constantly lurking without.

It is regretted that the photographic art does not show all shades of color in the pictures of variegated leaves. If the engraving could fully present the colors, the reader would not need to be told that the blighted portions of the several leaves shown are invariably upon the white or etiolated parts of the foliage. Upon these light areas the fungi, of which there are two, usually vieing with each other for the blanched territory, establish themselves and then spread to other and green parts of the leaf. These two fungi are indistinguishable except with a microscope. One of them is a member of the genus *Ascochyta*, and may be termed a genuine leaf-blight; the other is an anthracnose, and belongs to the genus *Collitotrichum*. It is difficult to convey an adequate idea of the structure and habits of these fungi without engravings to accompany the text. This is not the purpose of this article, but, instead, to account for the blighting of the Pelargonium leaves, which is due to these low forms of parasites being favored in their development by the blanched or non-green condition of parts of the leaves. Spraying with fungicides would doubtless assist in checking the growth of the fungous enemies.

Rutgers College.

Byron D. Halsted.

Notes on Shrubs.

IT is never safe to draw conclusions from or pass judgment upon one or two specimens of any species or variety of tree or shrub, or, indeed, of any other plant. This is especially true in testing hardiness, longevity, habit, productiveness or free-flowering character. When plants are received from nurseries it often happens that all the individuals of a kind are the progeny of one particular plant, and this may have peculiarities which are not common or typical to the species or variety as a whole. The variability shown in a large series of seedlings is often very interesting, and the extremes are frequently so different as to suggest the need of separate names. Indeed, such extremes have often been described as distinct species.

A look over a lot of seedling plants of our pretty and fragrant-flowered *Rhododendron arborescens*, or smooth *Azalea* of the Alleghany Mountain-region, exhibits marked variability

Blighted Leaves of Pelargoniums.

in certain directions, and shows how a purchaser of a seedling plant might get one which did not fulfill the expectations raised by a description of it. The flowers vary in color on different plants from a pure white to a very appreciable rosy tinge. There is a good deal of variability in the size of the

blossoms, but the abundance or scarcity of bloom on different plants is still more marked. Certain plants appear to have the habit of flowering much more freely than others, and of bearing the blossoms well above the foliage, which last is a result of less vigorous new growths or the habit of the plant to put its energies into the flowers instead of devoting them to the formation of long new shoots. Ordinarily, and when less abundant, the flowers of this species are somewhat obscured by the new growths and foliage. The botanist, of course, will find much variability in the minor details of the leaves, flowers, etc., but these are not generally interesting to the horticulturist.

R. arborescens has been compared with our northern Clammy Azalea (*R. viscosum*), and in some respects they are somewhat alike. The flower-buds of both are covered with hairs which are tipped with dark-colored viscid glands, but, as a rule, these hairs are most abundant on the Clammy Azalea. Great numbers of minute insects are often ensnared by the sticky secretion of the glands. The buds of both species are about the same length, but those of *R. arborescens* are stouter, and when they open the expanded blossoms they appear much larger than those of the other species, and this adds greatly to their beauty. While the stamens of the Clammy Azalea are usually white, with the pistil sometimes reddish, the stamens and pistils of *R. arborescens* are of a bright deep rosy red color, which is well set off by the white corollas.

It has been stated that these two species of Azalea are marked by a difference in the time of blossoming, and in the main this statement is quite true.

This season *R. arborescens* began to blossom here about the 20th of June, while the first flowers of *R. viscosum* did not open until quite ten days later. *R. arborescens* is now (July 10th) quite generally without a flower; but, among probably over a hundred plants raised from seed, there are two which are just in their very finest condition of bloom, being quite as late as any *R. viscosum*. Where lateness of flowering is a desideratum, such individuals as these might be well worth propagating if they are any improvement on the best-selected forms of *R. viscosum*; poor forms of this species are not worth a place in the garden, and are, perhaps, quite as variable as *R. arborescens*. Where a large number of seedlings can be seen together there will appear even a greater difference between individuals in thin foliage. The differences in foliage have been noted by botanists. A very common form has the leaves green on both surfaces, but a great many plants have foliage which is quite glaucous beneath, in which they resemble *R. arborescens*, while occasional specimens have the leaves glaucous on both sides. The leaves vary from being perfectly smooth on both surfaces on some plants, to those which have the upper surfaces of the leaves and the midrib beneath thickly covered with very stout appressed hairs or bristles, which are bent toward the apex of the leaf. The young shoots of this Azalea are clothed with stiff hairs, which are bent toward the end of the shoot, and this character is at once the best in distinguishing it from *R. arborescens*, in which the young shoots are quite smooth. In the best forms of the Clammy Azalea the flowers are about as large as small or medium-sized blossoms of the other. The plants are inclined to grow tall without spreading greatly, while those of *R. arborescens* in cultivation here, now eleven or twelve years old, from seed, are of a more dwarf, compact habit, with a spread of branches as great as the height, which is from three to four feet. Any peculiarly fine form of these Azaleas is much better propagated by layering than by any attempt at grafting by an amateur. *R. viscosum* is now sometimes freely used as a stock upon which to graft garden varieties, but it appears to have an annoying tendency to send up suckers.

Our Purple Azalea, or Pinxter-flower (*R. nudiflorum*), is well known for the variability in color of flowers which different plants exhibit in a wild state. By selection we may get plants of this species with flowers almost white, varying through flesh-color to pink or purplish.

The pretty *R. vaseyi* has been described as having flowers of a bright pink color, but a look over a lot of seedlings when in blossom in May shows much variation in the shades and depths of color, while several individuals here bore flowers which were almost white. An amateur horticulturist, who obtained through the Arboretum one of these seedling plants before it blossomed, expressed great disappointment that when it bloomed its flowers proved to be white instead of the bright clear pink which was desired. Such tendencies to variation among the different individuals of the several species of these pretty flowering native plants show very clearly that it is sometimes necessary to grow more than one seedling from a parent plant in order to exactly reproduce it in some desirable

even though typical, character, and that propagation by some form of division is the only safe and reliable way to perpetuate any peculiar characteristic.

Arnold Arboretum.

The Water Garden.

THE Water-lily ponds and basins are now the most delightful spots in the garden. Growth was somewhat retarded during the cold, backward spring, and this has had a marked effect on some plants, but the latter part of June was most favorable to their growth, and the result is at the present time a gorgeous display of all the hardy *Nymphæas* which come in for first honors. *Nelumbium speciosum* follows hard after them, its first flowers opening the second week in July, but they will be at their best when some of the hardy *Nymphæas* are past. The new varieties of the latter are rapidly increasing, and so is public appreciation of them, for the supply has not equaled the demand this spring. Besides the sorts of sterling merit described by Mr. Gerard in the issue of this journal for July 13th, I would mention *Nymphæa Marliacea rosea* as worthy of a place in every collection where even a few can be grown. The plant is vigorous, resembling *N. alba* in style of growth; the flowers are freely produced, and until late in the season its lovely cup-shaped flowers on opening are a tender rose color several shades deeper than those of the variety *Carnea*. When fully expanded the petals are much lighter, but they retain their color at the base.

The variety *Exquisita*, of *N. odorata*, has flowers more deeply colored than any other hardy *Nymphæa*. These flowers are large, of rich rosy carmine, and with delicious fragrance. The leaves are green on the upper surface, and intensely red on the reverse.

I consider *N. odorata sulphurea* one of the very best new hybrids. The plant is very vigorous for the odorata type; its large cup-shaped flower, standing out of the water, resembles a Lotus-flower in the distance. The color is more accurately described as a canary than as a sulphur yellow. It has light golden stamens, and petals narrower than those of *N. chromatella*, but longer and more numerous, while it retains the fragrance of *N. odorata*. The leaves are reddish on the reverse, heavily blotched with reddish brown. It flowers freely, and is a great acquisition.

Nymphæa pygmæa helvola is another hybrid of special merit. The flower is about three inches across, sulphur-yellow; petals longer, narrower and more pointed than those of *N. pygmæa alba*; the leaves deep green, blotched with reddish brown. It will be found very useful for tubs or small aquariums.

Nymphæa Laydekeri rosea is larger than the preceding variety, but is a most worthy novelty of the *Pygmæa* type. The flower on opening is a delicate pink, and the second day it is many shades deeper, the sepals retaining their whiteness. The stamens on the outside ray are rich yellow, while the centre ones are orange—a most pleasing combination of color. The third day the flower assumes a deep rose color. The plant is stronger than the type, and very free-flowering; it frequently shows flowers with all these different shades of color at once, as some of them open almost daily. These different colors are distinct enough to give the plant a novel appearance, as they inevitably suggest two or more kinds of flowers from one root.

Dongan Hills, N. Y.

W. T.

Alstroemeria aurantiaca.—The *Amaryllis* family is well represented in our gardens, but the genus *Alstroemeria*, which belongs to it, has few representatives in American gardens. The reason for this is that many of the species are too tender to endure our severe winters. One of them, however, grows vigorously here, and makes one of a group of striking beauty. *A. aurantiaca* is still flowering here, and only requires a covering of dried leaves in the winter. Three years ago I received two small tuberous-rooted plants, which I planted in a sheltered position in good deep sandy soil. They have grown so vigorously that they cover a space of three feet in diameter. I know several gardens where this plant has failed, but the reason of this is, without doubt, an unsuitable position or unsuitable soil. It is an important point to plant the tuberous roots deep in the soil, where the frost will not get to them. After they are established they should not be disturbed often. This *Alstroemeria* was brought from Chili in 1831. It grows about four feet high, and the stems are so stout that if it is grown in a sheltered position they do not require staking. The leaves on the stem are lanceolate-obtuse, and the petiole has a peculiar twist which inverts the leaves. The blossoms are large, orange-colored, streaked with red, and are produced in umbels of from twelve to fifteen flowers. Last year when I visited the

Royal Botanic Garden at Glasnevin, Ireland, I saw a most beautiful bed of these plants. At a distance it looked like a bed of dwarf Azaleas. Some of the species in this collection were Tricolor, Aurantiaca, Hæmantha, Simsii, etc.

Alstrœmerias can be grown either from seed or by division of the roots. The young seedlings require to be grown under

it adds another to an altogether too small a list of dwarf Harebells which will endure our severe winters. *C. rotundifolia* holds its own well and sows itself freely. It is a charming rock-plant, around which much sentiment clings since it is the true Bluebell of Scotland. *C. gargarica* planted this spring is blooming nicely, but it will need to be lifted in the autumn,

Fig. 60.—The California Locust (*Umbellularia Californica*).—See page 349.

glass for some time until they are strong before planting them in their permanent positions.

Botanic Gardens, Cambridge, Mass.

R. Cameron.

The Harebells.—*Campanula abietina* bloomed on our rock-garden for the first time this spring. It is comparatively new, from eastern Europe, and is a neat tufted species, with airy panicles of violet-blue flowers. It is particularly valuable, as

or we shall lose. This and its hirsute variety are often grown in pots, and may be commonly seen in cottagers' windows in England, suspended, their trailing branches sometimes hanging one foot or more.

Wellesley, Mass.

T. D. H.

Abortive Strawberries.—One cause of the formation of "nubbins" in Strawberries is, undoubtedly, lack of pollen. At the Cornell Station several Strawberry-blossoms were fertilized,

different flowers receiving unequal amounts of pollen. Perfect berries were formed by flowers in which all the stigmas upon the receptacle were treated. When only one-half of the stigmas was pollinated the fruit was smaller, the untreated half not having grown in any marked degree. What should have been the apex of the perfect berry was drawn over to the untreated half. Other flowers had about one-fourth of the stigmas fertilized. The berries produced by them were about as large as the preceding, but they were still more misshapen. The seeds were rather far apart, but otherwise the pollenized section presented a normal appearance. A seed would occasionally be missing, but this did not prevent the full development of that part of the receptacle. It was only where several seeds were wanting that a stunted growth was the result.

Cornell University.

E. G. Lodeman.

Galium aristatum.—This plant was sold a few years ago in considerable quantities as the Woodruff (*Asperula odorata*), from northern Europe, to which it has, in fact, very little resemblance. It grows to the height of three feet or more, and has large open panicles of minute white flowers on very slender stems. These panicles, when cut and used with other flowers, are very effective in softening and uniting their colors, as they surround them like a fine spray or mist. The flowers of the *Galium* also have the advantage of a delicate fragrance which faintly resembles that of Buckwheat-blossoms. When once established the plant takes care of itself and soon makes a large clump, which keeps in bloom in this latitude almost throughout the entire month of July. Much better known than this plant is *Gypsophila paniculata*, which also has small thread-like stems and small white flowers, which can be used for a similar purpose. It commences to bloom two or three weeks earlier than the *Galium*. Rather later than the *Galium* comes the best of the hardy *Statice* (*S. latifolia*), which is practically everlasting. No one who has once tried these plants will ever consent to do without them, for, although not strikingly beautiful in the border by themselves, they add grace as cut flowers to almost any others with which they are grouped. With these hardy perennials should be mentioned the little annual *Gypsophila muralis*, which has exceedingly fine stems and leaves and tiny pink flowers, and is also most useful in producing similar effects. Nothing adds so much to the beauty of a bunch of Sweet Peas as a few sprays of this delicate plant.

Montclair, N. J.

S.

Sobralias.

SOBRALIAS are not the most popular of the Orchids, but they are more thought of now than they were a few years ago, when the genus was seldom represented in collections. But they form a very interesting group, not difficult to grow, and although the flowers last but a few days in beauty, they open in succession, thus maintaining a prolonged display. One great charm of the genus is its distinct expression. The Sobralias are different from the majority of Orchids in flower and habit, and should therefore be grown if only for the sake of variety. The growth is slender, the leafage abundant, and each stem will bear on an average about six or eight flowers, varying, of course, according to the robustness of the specimen.

The Sobralias are terrestrial—that is, they belong to that group of Orchids which should be grown in pots, and the soil must be fairly open, so that the roots may run freely in it. Beginners in the cultivation of the Sobralia should provide plenty of root-space, larger even than in proportion to the plants, and for soil nothing is better than good fibrous peat, to which a moderate sprinkling of coarse silver sand has been added. The object of selecting somewhat lumpy peat is that the roots run freely through it, while the drainage should be liberal. It is not too much to fill pots, say, about eight inches in diameter, almost half full of crocks, those of smaller size to about one-third their depth, as without ample drainage it is hopeless to expect satisfactory growth or production of flowers. When the specimens become too large it is a very simple matter to divide them, and this affords a ready means of increasing the stock if so desired. The plants, when it is seen that they grow too large, should be turned out of the pots, the best portion of the old soil removed, and the tufts divided into moderate-sized pieces with the hand, as it is not advisable to use the knife more than is absolutely necessary. It is wise not to split them up too small, as it takes a long time for them to become established. The time for performing this work is the season at which repotting should take place—that is, when new growth is commencing—and it is one great point in repotting to make the new compost moderately firm, so that the water may

moisten thoroughly the whole ball. This is most necessary, as during the season of growth it is essential to give an abundance of water, even at the resting-period some moisture being necessary. Large plants of Sobralias are very beautiful, the reed-like growth and fresh green leafage having a peculiar charm in contrast to the delicately beautiful flowers, that are without a vestige of formality.

There are several kinds, the most familiar of which is *S. macrantha*, an excellent exhibition plant, and introduced from Guatemala and Mexico as far back as 1846, the variety *Splendens* following three or four years afterward from the same land. The type is almost too well known to describe. It must be a poor collection that does not contain an example, the stems about six feet in height, the flowers sweetly scented, large, measuring fully six inches in diameter, and rich crimson and purple in color, relieved by the pale yellow spot in the centre of the bold lip. There are several varieties, and allusion has been already made to the form called *Splendens*, so named from its richly colored flowers, although we may say that shape is sacrificed to color, the flowers not having the form of those of the type. *S. pallida* has very large blooms, delicate rose in color, the lip having a faint trace of color, and in "Woolley's" variety a conspicuous trait is the dwarf growth, the flowers also of great beauty. A very handsome species from British Guiana is *S. Liliastrum*, the flowers of which are large, white and yellow, appearing during the present month. *S. rosea* is very dark in color, the flowers quite of a mauve tone, the lip crimson, white in the centre; while in *S. xantholeuca*, a species of striking beauty, they are very pale yellow, the frilled lip of a deeper tone.

This is an age of new Orchids; and recently we have had a notable addition to the Sobralias in *S. Lucasiana*, which was awarded a first-class certificate at the meeting of the Royal Horticultural Society on June 21st last. It was shown by C. J. Lucas, Esq., Warnham Court, Horsham, whose collection is of great interest. As regards habit, *S. Lucasiana* is much like any other Sobralia, the growth moderately tall, very bushy, and the flowers of characteristic shape. They are very compact in shape, the sepals white, faintly touched with rose, the petals broader, and deeper in color; the lip is of splendid shape, round, very broad across the central lobe, and rich purple-lilac in color.—*Gardeners' Magazine*.

The Forest.

The Forest as modified by Human Agency.—I.

FROM an introduction to a course of forestry-lectures, delivered before the University of Edinburgh in their session 1891-92 by Colonel Bailey, University Lecturer, Conservator of Forests and Director of the Indian Forest School, printed in part ii., vol. xiii., of the *Transactions of the Royal Scottish Arboricultural Society*, which has just reached us, we have made the following extracts, which appear to be of general interest as bearing on the question of forest-preservation in the United States:

"In early times the greater part of the dry land was, no doubt, covered with trees and shrubs of various kinds, each kind flourishing and maintaining itself in the locality best suited to its special requirements. As the older trees fell to the ground their places were taken by others of the same or of associated species, which grew up in the openings thus afforded to them, and an unbroken succession of trees and shrubs was in this manner maintained; for at that remote period but few of those destructive agencies were at work which have raised forestry to a science.

"What is the foremost among these destructive agencies? Unquestionably man.

"It is no doubt true that natural phenomena, such as storms of wind, have always occurred from time to time; but the forest-growth would, in most cases, surely, if slowly, re-establish itself after each visitation, and the damage done by four-footed animals, insects and noxious fungi would not be likely to make much impression on the vast extent of forest which then covered the earth's surface. The human population of the world was small, and the requirements of men were by no means so varied and extensive as they are at present. But as population increased, man had to extend the small patches of cultivation which were the scene of his first efforts in the art of agriculture, and he wanted timber and fire-wood for domestic use. He also needed grazing-grounds for his flocks and herds. Then, in course of time, he began to build better houses with larger timber; he made boats and ships; and later on he constructed railways, and developed numerous in-

dustries which consumed vast quantities of wood of all species, qualities and sizes; at the same time he largely extended his cultivation and increased his flocks and herds; and before every one of these advances portions of the natural forest went down and disappeared forever from the face of the land. But the process was a very gradual one, extending over many centuries. It proceeded slowly at first, and not until comparatively recent times did the country begin to assume its present appearance. It is not so very long ago that the road from London to Edinburgh was an unsafe one to travel over in consequence of the gangs of robbers who found shelter in the thick forests through which it passed. Do not misunderstand me to pretend that these changes from denudation have in general been for the worse; you do not require me to tell you that up to a certain and, indeed, a very advanced point they were very much for the better.

"Long before this stage of development had been reached, however, a time had come when it was found impossible for every one to continue to help himself with a free hand; claims to ownership of forest and waste lands had been set up, and established by the law of might, and some sort of restrictions had begun to be enforced. But these were quite inadequate to arrest the progress of the destruction of the natural forest, which at length reached a point at which the supply of forest-produce became insufficient to meet the requirements of the population; and measures then began to be taken not only to secure some tracts of forest from further encroachment, but also to increase the wood-bearing area by sowing and planting. But it is not to measures of this nature that many of our largest forests owe their existence at the present day. Their continued maintenance is due rather to the protection they received under strict laws for the preservation of game than to any endeavor to guard them for the sake of the timber they could yield. The New Forest in Hampshire is a good example of this, and the same may probably be said of the Windsor Forest and of the Forest of Dean in Gloucestershire, as well as of others in Scotland.

"It will easily be understood that the countries in which civilization advanced with the most rapid strides were those from which the natural forests disappeared the soonest; and at the present time these islands have a smaller percentage of wood-producing area than is found in any other European country, with the solitary exception of Denmark. The actual proportion is as follows:

Russia,	40 per cent.	Greece,	14 per cent.
Sweden,	34 "	Spain,	7 "
Norway,	29½ "	Belgium,	7 "
Germany,	26 "	Holland,	7 "
Turkey,	22 "	Portugal,	5 "
Switzerland,	18 "	British Isles,	4 "
France,	17 "	Denmark,	3½ "

The average is 29½ per cent., and includes orchards and isolated trees in parks, hedge-rows and elsewhere.

"Countries which, like ours, have a very small wooded area of their own, have to supplement their home-grown supplies of wood from other countries which are still able to produce more of this commodity than their population can consume; and, on reference to Dr. Schlich's *Manual of Forestry*, I find that the United Kingdom annually imports

Timber to the value of about	£15,000,000
Minor forest-produce to the value of about	8,000,000
Total, about	£23,000,000

"These facts have not, up to the present time, led to any very great amount of inconvenience: (1) because our insular position affords us great facilities for the importation of timber; (2) because we have a plentiful supply of coal; (3) because our climate does not demand modifications of the nature which extensive forests are able to effect, nor do we, as a rule, suffer from any deficiency of the water-supply in our wells, springs and streams; and (4) because the geological formation and the configuration of these islands, and the climatic conditions under which we live, do not render it as necessary as it is in many other countries, that large areas should receive the protection against the effects of violent and continuous falls of rain, which is so well afforded by a crop of trees and shrubs.

"It is true that a part of Scotland has recently suffered severely from floods; but the effects of these floods bear no comparison with those produced by denudation in some other parts of the world, where the rain is heavier, the sun hotter, and the rock and soil are less consistent than with us.

"While employed by the Secretary of State for India at the French Forest School at Nancy, I visited the southern French

Alps, which have been subjected to excessive grazing, and from many parts of which not only the trees and shrubs, but even the very grass had disappeared. The surface is, therefore, no longer bound together by roots; and when the heavy semi-tropical rain falls directly upon it the soil, and subsequently the loose rock, slips down into the valley below. The water charged with these substances runs off with great rapidity, and suddenly fills the torrent-beds. These latter soon become deepened by the 'scour,' when their sides, deprived of support, fall in; and the effect of this action, going on throughout the whole system of water-courses which traverse the mountain-sides, is that, over enormous areas, the upper strata of the soil, with its fields, houses, and even villages, are borne down into the valleys, and the whole region, which presents to the eye little but a series of unstable slopes of black marl, has an extremely desolate appearance. But the damage does not stop here; for the debris is carried down to the comparatively level valleys and open country below, where it is deposited over fields, roads, railways and villages, thus doing an enormous amount of harm.

"In order to mitigate these terrible evils, the French government has undertaken the vast enterprise of regulating the torrent-beds by means of engineering works, and of afforesting the mountain-slopes over an area of more than a thousand square miles, including nearly two thousand linear miles of torrent-beds. The cost of such an undertaking is, of course, very great, but the circumstances warrant the expenditure.

"A very similar condition of things prevails in the Hoshiarpur District of the Punjab, on which I had a short time ago to submit a report to the government of that Indian province. I have conversed with men who remember this range of hills covered with trees and tall grass, which were the home of the tiger and other wild animals; but now there is hardly a blade of grass to be seen, and the hills are gradually being washed away and deposited on the plains below. I am told that the bed of the Mississippi is being blocked by sand and soil brought down from the mountains of the 'Far West,' in consequence of the extensive clearings that have been made there during recent years.

Correspondence.

Vernon Park, Philadelphia.

To the Editor of GARDEN AND FOREST:

Sir,—Some time ago I promised to give an account of what we were doing about Vernon Park, but as usual there is a struggle with some personal interest when any good thing for the public is to be accomplished, and in this case we have had on our hands a lawsuit with some disaffected citizens. The case is now decided, however, in the city's favor, and on the 1st of July we placed the property in charge of a city superintendent.

This little park contains about eight acres, and among the areas for small parks we have taken, it is second in importance only to Bartram's Garden. Being in the heart of the Germantown district, or the twenty-second ward of the city of Philadelphia, it is just where the lover of trees can have an opportunity to see some grand old specimens, and convenient to the poor people and their children, who wish a breath of fresh air and an open space to enjoy themselves in. Before this place fell, providentially, into the hands of the Wisters, who have preserved it, it was owned by an old Philadelphia banker named Meng, who was among the very early patrons of gardening hereabout. He was the chief patron of Kin, who was one of the first botanical collectors in the then dangerous wilds of America, though, singularly enough, his name has never been honored as have those of Rafinesque, Nuttall, Lyon, Pursh and others, possibly because he was in a measure isolated from the public by his German connections. He appears to have been sent here by some patrons from Germany, and his American specimens are still preserved in the Botanical Museum at Berlin, as I am advised by Professor Krug. Some of the first specimens of our rarer Alleghany trees were introduced here by him. Undoubtedly the earliest cultivated *Magnolia macrophylla* is here, and it was brought here by Kin. It was, unfortunately, struck by lightning some years ago, and the exposed wood down the trunk of the tree which was not painted to keep out the water has decayed from one side. I think, however, the good gardener, who, in these days of political appointments, has been fortunately selected to superintend these grounds, will arrest further decay, and that the great wounds will heal over, a result which the good tree is now bravely trying to effect.

The park is not paid for. When I first began this small-park campaign on our city my plan was to negotiate with the owners of the ground so as to make the best bargain possible for Philadelphia. For the first little square we took, that of Weccacoe, the owners demanded \$20,000. It was a small plot, but I had it taken so as to make a precedent of getting possession of abandoned grave-yards. I and my colleagues, five of us, who were a Committee of Councils, considered \$10,000 an adequate payment, and we therefore had an appropriation of this sum made, and offered it to them. The owners finally took this amount, and yet it was freely stated that part of this money was needed to defray the "cost of getting the matter through Councils"; and this accusation was spread by the attorney of the owners, who is said to have received \$1,200 for his services. It was very evident that, no matter how honestly public business of this kind is conducted, there will always be a suspicion that there is a job in it. Since that time I have changed the practice, and land is now taken by award of a jury regularly appointed by the court, and the money to pay for these lands is raised by the usual process of mandamus on the city treasury. This is the only way to protect ourselves against ungenerous accusations. Vernon Park will probably cost nearly a quarter of a million of dollars, but public-spirited citizens have already subscribed one-tenth of the sum in view of its advantages and size.

I once looked upon these breathing-places for the poor in large cities with the eye of an artist, valuing them primarily as spots of beauty and ornament to the city. It was my desire that they should all be educators in taste and landscape-art. I still would have them beautiful, provided this did not interfere with the real needs of the poor. I look upon them now as playgrounds and places where all kinds of physical recreation can be enjoyed, and I leave the details of garden beauty and the ornamentation of the city to take a subordinate place.

Fortunately for our Vernon Park, while lovers of the beautiful in nature, as well as those who delight in historical associations, will have full satisfaction in it, about one-fourth of the whole space is open lawn, which will be so arranged that the children can romp and play on it and enjoy themselves as they will.

Germantown, Pa.

Thomas Meehan.

Gardens in Northern Germany.

To the Editor of GARDEN AND FOREST :

Sir,—As the Forest Department of the German cities is a distinct branch of the municipal government (see GARDEN AND FOREST for May 4th, p. 214), so is the Field Department also a separate organization, in which is included the official oversight of the suburban gardens, which are found in every direction, either adjacent to the main promenades and shaded walks, or further away, where they were established often many years ago. No one ever hears it said in those cities, "I am going to make a garden this year." A piece of land once a garden is always a garden there, and by good management it increases in value yearly, and is kept in the family for generations. The country abounds in numerous lakes and rivers, great and small, and care is generally taken to place the gardens close to the water's edge, so that steps may lead down to it, or a platform extended over it, and provided with seats for the members of the family. Here angling is also a favorite pleasure. The waters abound with fish of all kinds, and a floating fish-box is a certain and necessary article in the household, so that fish may be kept fresh in their natural element; nobody eats fish which are purchased after they are dead. Laws in relation to the taking of fish out of the waters are strictly enforced, so that the future generations may also have an abundant supply. The largest fish are not taken, but left in the waters for propagation.

The fertility of the garden-soil is kept up by carefully saving all waste and every fertilizing product. The waters are not polluted by sewage. The gardens are generally divided by hedges, but of late wire fences are also much used because they are cheaper and need less care. The wealthy and more prominent people have houses built where garden-parties are held; others have only small, but quite ornamental, cabins or rustic arbors for holding their tools in security when not in use. The land is spaded, for the trees and different berry and flower bushes will not permit the use of horse and plow. A family garden contains little or no turf; every bit of ground is made to produce its utmost. All beds are laid out in straight lines, and the various vegetables are set where each can secure the amount of sunshine and shade it needs. Most people have two gardens, one of them called the wet garden, where they raise their cabbage and vegetables for winter's use. Often

a part of those outlying gardens is sowed with Flax, also for family use.

The work is mostly done by women. In fact, their life and that of the children, when they are not at school, is practically spent in summer in the garden. Without any special effort the younger generation in this way becomes acquainted with all kinds of practical garden-work and knowledge of natural history. The natural sciences, and especially botany, are taught in the public schools, and when a plant or insect unknown to a child or its parent is discovered it is preserved, and the next day sent to school to be identified by the teacher. Woe to him if he cannot give the needed information. His whole influence and reputation are lost. This is a serious matter, for schools are not free, and the parents, who have to pay for the tuition of their children, are keenly interested and anxious to find out whether they are getting their money's worth of instruction. My observation in this country leads me to suspect that the people most benefited by free schools appreciate them but slightly, considering, perhaps, that anything which costs nothing must be worth little.

Hartford, Conn.

Wilhelmine Seliger.

Wintering Half-hardy Plants.

To the Editor of GARDEN AND FOREST :

Sir,—The possibility of growing out-of-doors many more things than we do by protecting them in winter, as suggested by Professor Massey, is an interesting subject, and I have no doubt that many plants could be added to those now cultivated in almost all localities. There are here specimens of the *Melia Azederach* and *Bumelia tenax*, which were coaxed along at first by a little shelter in winter, and which are now taking care of themselves. Last winter the following plants were left out without any protection beyond that afforded by large shrubbery, and all are thriving to-day: *Cleyera Japonica*, *Lycesteria formosa*, *Choisia ternata*, *Ilex Cornuti*. Figs and Pomegranates. The *Cleyera* and *Ilex* were entirely unhurt, *Choisia* and Pomegranate partly killed back, and Figs killed to the ground. No covering of any kind was given to any of these plants, and it is probable that a little protection would have saved them all. Mrs. Dandridge speaks of the *Abelia rupestris* doing well at Washington. I may add that it thrives at Germantown. Where shrubs are grouped as at Washington and sheltered by large buildings many partly tender kinds can be easily carried through the winter. I have there seen fine *Aucubas*, English Hollies, English Laurel, *Abelias*, evergreen *Magnolias*, *Acacia Julibrissin*, and similar plants massed together, one protecting the other, and all thriving because of this protection.

Germantown, Pa.

The Cultivated Native Plums and Cherries. Bulletin 38, Cornell University Agricultural Experiment Station, Horticultural Division. L. H. Bailey. Pp. 1-73; 14 figures.

In his introduction to this important paper, in which are printed the results of six years of careful study, Professor Bailey tells us that "since the introduction of the Wild Goose Plum, some forty years ago, there has been a steadily growing interest in the amelioration of our native Plums." Of these at least one hundred and fifty named varieties are now recognized by pomologists; and it was the attempt to classify these and refer them to wild types which led Professor Bailey to undertake a critical study of all the Plums of probable American origin found in our gardens and orchards.

Eastern North America contains six species of true Plums which are either native to the soil or have become entirely naturalized. Of these nothing need be said now of *Prunus Alleghaniensis*, a local Pennsylvania species, or of the southern *P. umbellata*, for, although the fruit is collected from the wild trees of these species and is sold in the markets of the regions which they inhabit, they are not known to have given rise to any recognized garden varieties. Of *P. maritima*, the Beech Plum of the Atlantic coast, little, too, need be said, for only a single variety of this plant is cultivated for its fruit, and this, apparently, is of no great value, and is hardly superior to the fruit produced ordinarily by the wild plants of this species. The other cultivated Plums derived from eastern American species, or from naturalized species, Professor Bailey arranges as follows:

- a. The Americana group.
- b. The Wild Goose group.
- c. The Miner group.
- d. The Chickasaw group.
- e. The Marianna group.

In his first group the author arranges "the hardy strong-growing varieties which have come from the north-west, and which are characterized by a firm, meaty, usually compressed, dull-colored, late fruit, with thick, and usually very tough, glaucous skin, and large, more or less flattened, stone, which is often nearly, or quite, free, and by large obovate, thick, veiny, jagged dull leaves." The plants of this group are referred to the *P. Americana* of Marshall, with which Professor Bailey unites the so-called Canada Plum, which Aiton described a century ago under the name of *P. nigra*. It is true that some of the cultivated varieties which obviously belong in this group show in the herbarium characters which are intermediate between those of the wild types of the Canadian Plum and of the species of the middle, southern and western states, upon which Marshall bestowed the name of *P. Americana*; but as the two trees appear growing wild, one in the north and the other in the south, they differ so constantly in habit, in the time of flowering, in the size of the flowers, in the character and covering of the calyx-lobes, and in the form of the stone of the fruit, that it is impossible to believe that they can be specifically united from the point of view of the botanist.

In the *Americana* group forty-five varieties, now pretty generally distributed in cultivation, are described. The plants of this group are said to succeed best in the northern states of the Mississippi valley, and they are the only ones which are able to withstand the climate of the northernmost limits of the native Plum-belt, as Wisconsin, Minnesota and Iowa. There are some varieties, however, which succeed as far south as Texas, although in the Atlantic states the varieties are not grown far south.

We suspect that the varieties that succeed in the extreme north-western states will be found to have sprung from the Canadian Plum, which was brought into New England at a very early day, probably by the Indians, and where it has now become established in many places in which it is not probable that it grew naturally. It is possible, therefore, that this tree was carried by the Indians or the early voyageurs into the region beyond the Great Lakes, and that it was from these introduced plants that some of the varieties now esteemed by the pomologists of Wisconsin and Minnesota have descended. Certainly it is hard to find any trace of the *P. Americana* of Marshall in such trees as Weaver and Purple Yosemite, while in De Soto, Cheney and Forest Rose it is difficult to discover the blood of *P. nigra*.

The Wild Goose group, which is considered by Professor Bailey "the most important group of native Plums, includes varieties characterized by strong wide-spreading growth and mostly smooth twigs, a firm, juicy, bright-colored, thin-skinned fruit, which is never flattened, a clinging, turgid, comparatively small, rough stone, which is sometimes prolonged at the ends, but is never conspicuously wing-margined, and by comparatively thin and firm, shining, smooth, flat, more or less Peach-like, ovate-lanceolate or ovate long-pointed leaves, which are mostly closely and obtusely glandular-serrate, and the stalks of which are usually glandular." The species from which this group is evidently derived has only been recently recognized by botanists, and it is Professor Bailey himself, in a recent issue of this journal, who raised to specific rank, under the name of *P. hortulana*, the Plum-tree of the middle Mississippi region which earlier botanists had confounded with the Chickasaw Plum, a plant of a more southern origin.

In the *Hortulana* group Professor Bailey finds two more or less clearly marked types, one characterized by thin and very smooth Peach-like leaves, which are finely and evenly serrate, and the other by thicker, duller and more coarsely and irregularly serrate leaves. In the first of these groups is placed the Wild Goose Plum, which was first brought to notice by James Harvey, of Columbia, Tennessee. The history of this variety, which is the most popular probably of all the native Plums and the one which has done more than any other variety to extend their cultivation, is, as Professor Bailey tells it, as follows: "The Wild Goose was first brought to notice by James Harvey, of Columbia, Tennessee. Some time before 1850 a man shot a wild goose near Columbia, and on the spot where the carcass was thrown this Plum came up the following spring. It was introduced about 1852 by the late J. S. Downer, of Fairview, Kentucky. This is the first Plum introduced into general cultivation, although the Miner was first known and named." Plants of the Wild Goose type, as a whole, appear to be best suited to the middle latitudes, being grown with satisfaction from Illinois and Indiana, and the southern part of Michigan and New York to Maryland, Virginia and Tennessee, and in the south-west to Texas. The varieties which are most highly prized are Golden Beauty, Indian Chief, Missouri Apricot, Moreman, Wayland and Wild Goose.

The Miner Group, as defined by Professor Bailey, "includes a few anomalous varieties, which appear to be intermediate between *P. hortulana* and *P. Americana*. They may be an offshoot of *P. hortulana*, or it is possible that they constitute a distinct species. The Miner is particularly well marked, but there are others which it is sometimes difficult to separate from *P. hortulana*." To this group are referred Clinton, Idol, Miner and several others. It is described as a strong and hardy race, which is particularly adapted to the northern limits of the cultivation of the *Hortulana* family. The varieties are much alike. The Miner is the most popular member of the group, and it succeeds even in northern Illinois. In New York the varieties ripen from late September to late October.

The members of the Chickasaw group, derived from the so-called Chickasaw Plum, the *P. angustifolia* of Marshall, differ from the plants of the Wild Goose group "by a more slender, spreading and zigzag growth, usually smaller size of tree, red twigs, by smaller, lanceolate or oblong-lanceolate, very closely serrate shining leaves, by early small flowers, which, upon old wood, are densely clustered upon the spurs, and by an early red or rarely yellow and more or less spotted translucent fruit, the flesh of which is soft, juicy, and more or less stringy and very tightly adherent to the small, broad, roughish stone." Professor Bailey is of opinion that the type of the Chickasaw Plum grows wild from southern Delaware to Florida and westward to Kansas and Texas, although it has usually been considered an introduced plant in the eastern states, where it is generally found growing in the neighborhood of dwellings or along the borders of cultivated fields—that is, in situations to which it might have been expected to escape from gardens. Michaux, the French botanist, who resided in South Carolina toward the end of the last century, was told there that the Chickasaw Plum had been brought from the West Indies, and there are many indications which point to the southern origin of this plant, although it is fair to say, in support of Professor Bailey's theory, that it is not known anywhere outside the limits of the United States. We should suspect, from its inability to support cold and its truly domestic habits, that it had been brought into the southern states, perhaps, before the coming of Europeans from the high lands of Mexico or from some Andean region, although, if this had been the case, it is remarkable that it has never been found growing wild in those countries. It is the small-sized fruit of the wild or naturalized bushes of this species which is sold in the markets of the middle states as Mountain Cherries. Eighteen varieties of this group are described by Professor Bailey, who finds them particularly adapted to the southern states, the leading varieties being Caddo Chief, Jennie Lucas, Lone Star, Pottawattamie and Yellow Translucent.

In the Marianna group are placed the Marianna and the De Caradeuc Plums, and probably also the Hattie. These form a distinct class, "differing in habit of tree, very early flowering, elliptic-ovate, rather small and finely serrate dull leaves, glandless leaf-stalks, and soft spherical very juicy plums of a 'sugar and water' character, and broad ovate stones which are scarcely pointed and are prominently furrowed on the front edge." These plants, which have long perplexed pomologists, Professor Bailey believes are derived from *Prunus Myrobalan*, an Old World species, probably of eastern origin, although long considered by European botanists a doubtful plant, and once considered an inhabitant of the New World. It is evident, however, that it is not American, although it has been cultivated in this country for many years, especially as a stock upon which to graft the varieties of the Old World *P. domestica*, and it is doubtless from such stocks that the varieties of this group have been derived.

Professor Bailey describes and figures, too, the dwarf Cherries, which either for the beauty of their flowers or the promise of their fruit are now attracting attention among horticulturists; he explains the methods best suited for cultivating and propagating our wild Plums and Cherries; he discusses the fungal diseases which infest them, and the insects which prey upon them, and tabulates the estimates obtained from representative growers in all parts of the country of the value of the leading varieties of Plums.

Pomologists and botanists will find in this paper a mine of information, and the author has earned their thanks for cutting what he very rightly describes as "the hardest knot in American pomology." Certainly before the result of his investigations was made known no group of plants cultivated in America was so inextricably confused or so difficult to understand as the American Plums, and in future, although much additional information will, no doubt, in time be gathered about them as they are more generally appreciated and cultivated, every serious pomologist must begin his investigations

of these plants by the study of Professor Bailey's paper, which is one of the most important contributions to American garden literature which has appeared in recent years.

Notes.

A correspondent of the *American Florist* writes that Mr. Robert Craig considers Mrs. Whilldin the best early Chrysanthemum. Mr. W. K. Harris, on the contrary, thinks that Eldorado is the best market flower of the early yellow varieties.

Governor Russell, of Massachusetts, has appointed Charles Francis Adams, of Quincy, Philip A. Chase, of Lynn, and Wm. de las Casas, of Malden, members of the Metropolitan Park Commission, which is constituted to report to the next Legislature a plan for a system of ample open spaces for the cities and towns in the vicinity of Boston.

We have a note from Messrs. Thomas Meehan & Sons saying that if our correspondent quoted on page 348 had sent for all the catalogues advertised in our columns he would have found that the Prairie Rose was on sale at one establishment at least. Rosa setigera has been offered for many years by Thomas Meehan & Sons, of Germantown.

Mr. A. J. Drexel, of Philadelphia, has recently presented to the Horticultural Commissioners of the World's Fair a remarkably fine specimen of *Licuala grandis* from his private collection. The plant in question is in a sixteen-inch pot, and carries twenty-eight leaves, and is without doubt one of the finest examples of this rare Palm in the United States.

Young trees of *Robinia viscosa* have made a strong growth this year on account of the abundant rainfall, and the new shoots are now bearing a second crop of racemes of bright rose-colored flowers. This tree seems to be more popular in European gardens than it is in its native country, but its excellent habit, good foliage and attractive flowers commend it where trees of medium size are needed.

The diploma of the German Society for the advancement of horticulture has been bestowed upon Herr Kittel, of Eckersdorf, for a hybrid *Vriesea* (*V. hybrida pommer Escheana*), the offspring of *V. psittacina Morreniana* and *V. splendens*, which the judges described as superior to either of its parents, and in both habit and flower an exceptionally interesting novelty, adapted to cultivation by amateurs as well as florists.

At this season, when shrubs in flower are rare, *Cytisus nigricans* makes a very bright show with yellow pea-shaped blossoms on its erect and slender branches, which rise to the height of eighteen inches or more above the ground. It has been long cultivated in the gardens of Europe, but for some reason it is still rarely seen in America, although it is perfectly hardy and very desirable among dwarf-growing shrubs, of which we have none too many.

Baron Todaro, Professor of Botany in the University of Palermo and Director of the Botanic Garden of that city, died on the 18th of April, and has been succeeded by Dr. Hermann Rast. Todaro is known by his publications on various species of the Cotton-plant, on Agaves, Aloes and other plants cultivated in the Palermo garden. In addition to his scientific pursuits, he was a lawyer of reputation, and was actively interested in the political affairs of his country.

In the ancient days of Rome a bride always gathered with her own hands the flowers which were to form her wreath. Ordinary torches were made of Fir or Pine wood, but the torches carried in wedding processions were of the wood of the White Thorn, as this tree was sacred to Ceres and was considered a talisman against evil; and, upon entering their home, the newly married pair knelt together by the hearth and lighted their fire with one of the White Thorn torches.

The Horse-chestnut and our native Buckeyes are among the early-blooming trees, but the Dwarf Buckeye (*Æsculus parviflora*) has the advantage of blooming when shrubs in flower are not abundant. This plant, which is a native of our southern Alleghany region, attains a height of from six to eight feet, and spreads in a few years to make a bush ten feet in diameter, and from this mound of bright green foliage rise in late July hundreds of tall cream-white flower-spikes which give the shrub a most striking appearance.

"No effort to create an impossible or purely ideal landscape," says Mr. Lafcadio Hearn, "is made in the Japanese garden. Its artistic purpose is to copy faithfully the attractions of a veritable landscape, and to convey the real impression that a real landscape conveys. It is, therefore, at once a pic-

ture and a poem; perhaps even more a poem than a picture. For, as nature's scenery, in its varying aspects, affects us with sensations of joy or of solemnity, of grimness or of sweetness, of force or of peace, so must the true reflection of it in the labor of the landscape-gardener create not merely an impression of beauty, but a mood in the soul."

Former attempts to transplant Cocoanut-trees from the tropics to the greenhouses of San Francisco have been unsuccessful, but the authorities of Golden Gate Park hope for a better result with a fine specimen which recently arrived there. It came as a present from Queen Kapiolani of the Hawaiian Islands, and was the best specimen which could be procured within easy distance from the port of Honolulu, the object being to secure a fruiting tree not too tall for transportation. It is about thirty feet in height. Its branches were so carefully packed in sacking that neither the leaves nor the fruit were injured, and its roots were protected by a strong box. It was brought by horse-power from its native spot to the coast, and again from the wharf at San Francisco to the park. Great haste had to be used to prevent its being chilled by the cold Californian winds, but in three hours after its arrival at the park it was safely housed in the main gallery of the greenhouse. It is the largest example yet brought to San Francisco, but promises to live and thrive.

An article on the Great Pine of Japan, called *Dai Matsu*, which stands on the coast of the inland sea of Biroa, about three miles from Otsu, was recently published in *Gartenflora*. It says that the priests who have charge of the tree declare that it was mentioned in the records of their cloister eight hundred years ago, and that it was planted in the year A. D. 675. It is counted among the eight wonders of Japan, and its singular aspect, as it stretches its long branches far out on every side over a scaffolding formed by more than three hundred poles, has been pictured in many books of travel. Although it is fully exposed to the wind, and although its trunks and branches bear more than one lightning-scar, it is still vigorous, and only a gradual thinning-out of its foliage bears witness to its great antiquity. At two feet above the ground the diameter of its trunk is fifteen feet nine inches; its height is eighty-four feet, and the diameter of its widely-stretched crown is 242 feet. Four houses formerly stood among its branches, but two of them were ruined in a great storm a few years ago. The other two are still largely resorted to by supper-parties on summer evenings, and the Japanese take especial delight in listening to the dripping of rain into the water from the boughs as they overhang the sea. The writer of this article could not definitely ascertain to what species of Pine the famous tree belongs, but says it is possibly an example of *Pinus densiflora*, or more probably of *P. Thunbergii*.

"The art of the Japanese gardener," writes Sir Edwin Arnold, "had turned our little plot of a couple of acres into the appearance of a large and various pleasure-land, with miniature hills—from which you could see the towering snows of Fuji San—fish-ponds, rock-works, trellised arbors, and clumps of flowers and bushes, which gave us an unbroken succession of floral wealth. Scattered about the grounds were stone lamps called *Ishi dōrō*, and grotesque demons, and quaint water-cisterns in stone with Chinese inscriptions. Around these first came into bloom, defying snow and frost, the beautiful red and white and striped Camellias. When these had fallen the white and pink and rose-red Plum-flowers filled the eye with beauty. Afterward the Azaleas blazed, like burning bushes all round the Lotus-pond; and these were followed by a delicious outburst of pale, rose-tinted Cherry-blossoms, making an avenue of beauty and glory all the way from the Shinto temple at our gate to the front door, where were suspended the little, indispensable, but useless fire-engine and the bronze gong on which visitors beat with a little wooden hammer to announce their arrival. The *Wistaria* and a second crop of Camellias, and then some red and yellow roses, took up the running, and the Maple-bushes came out resplendent with blood-red leaves; after which there were purple Irises and Callas flowering by the fish-pond, with orange and red Lilies brighter than the gold-fish swimming in it, and the lawn became covered with a pretty little flower called the *Neji-bana*, the pink buds of which, growing diagonally and reaching round to get the sunlight, twisted the stem into the shape of a corkscrew. Thus, along with the sprays of the Firs and Loquats and ornamental shrubs, our gardener—whom we christened the 'Ace of Spades,' out of 'Alice through the Looking-glass,' and who wore a blue coat with white dragons upon it—was never destitute of delightful material wherewith to exercise the high art of decorating our rooms after the great æsthetic Enshin fashion."

Foes to Country Road-sides.

AMONG the enemies from whom the country highway needs protection the road commissioner and the electric agent are the most dangerous. The former has town authority for his vandalism, but the other marauder commits his depredations in defiance of law, and, consequently, ought to be met by organized opposition. Statutes declare that a proprietor is master of the land that abuts upon his boundaries so far as the middle of the highway, and that he has a right to its grass, its fruit, and to its possession in case the road should ever be discontinued. The town has a right to take what is necessary for the highway, and no more, to which end it may cut down trees and shrubs, plow up grass, and take other liberties at its discretion. The authorities are very apt to stretch a point in this matter, for instances are known where whole rows of stately trees have been sacrificed for the sake of a prospective road which was afterward abandoned, while all entreaties of the owners are disregarded as interfering with the town's right of eminent domain.

Another depredation is permitted also to that foe of natural grace and beauty, the road-commissioner, whose mistaken zeal is allowed annually to remove the grass which seeks to soften the dusty outline of the road along its untrodden borders and gutters. This is an expensive process and wholly unnecessary, since adding to the dust-capacity of the street is the only service it accomplishes, the short, thick turf affording no obstruction to carriage-wheels. This is called "cleaning-up" the street, when, as a matter of fact, it only adds to its dirt. But a worse phase of the cleaning-up mania is apparent when the zealous commissioner proceeds to remove from the banks of the highway what he terms weeds—namely, the graceful mantle of vegetation with which nature ever seeks to conceal the wounds which man has made. It is interesting

to watch the process by which the devastations of the road-cutter are tempered to the eye by the beautiful natural screen of vines and herbage, which, if let alone, will soon cover the rough unsightly places with a drapery of verdure when the reckless workman has left behind him a shorn and barren waste. After his inroads, banks of sand or gravel are left on either side of the wide road, from which every spear of grass has been banished, the fences stand up stiff and stark, the rocks protrude from the soil, the trees which cannot be felled have their lower branches rudely cut away, so that their trunks are gaunt and unsightly; stumps are left along the edges of the fields, and the soft turf is replaced by sandy slopes to be gullied by the rain. Without wasting an hour Nature begins her gentle but tireless work of transforming these ruins into beauty. What can be more pleasing than the unmolested edge of an old road, where Hazel and Elder hang out their fruit for the birds, where the fragrant Clethra blossoms, where the wild Grape-vine and the glossy Bramble climb from tree to tree, and wild Roses and Morning-glories brighten the shadows with their smiles. Here in the spring the Trientalis and Anemone make the ground beautiful with their white blossoms, while the Shad-bush waves a welcome to the passer-by. As summer comes the sky-blue Chicory clusters there, the Milkweed and the Epilobium show pink and purple amid the foliage, the Mullein lifts its stately yellow blossom from its furry leaves, while the Barberry shows first its arcs of yellow bloom and later its coral clusters of fruit, that contrast well with the great Golden-rod and the splendid purple of the wild Aster in the fall.

The leafage is dense and varied. Sweet Fern and Bayberry add to its fragrance with their aromatic odors; the Alder waves its tassels; the Swamp Willow lifts its lance-shaped leaves after the catkins are gone; now and then there is a whiff of fragrance from an Azalea which gladdens the hot breezes of July from a neighboring swamp; Ferns and young Pines struggle together in their infancy, and here and there a feathery Hemlock rises under the protecting shade of other trees, where it loves to hide from the sunlight.

The panorama, as you drive or walk, perpetually changes, reveals new charms, hidden beauties, in a wealth that a gardener might envy. Everything, from a Buttercup to an Orchid, may be found along the highway border, while the thrushes and the song sparrow call among the bushes, and the saucy squirrel scolds from the bending boughs above.

All this is scorned by the thrifty farmer as a nursery of weeds and disease for his crops, and nominally in his interest the mower walks abroad with his brush-hook and makes havoc of this charming scene which we enjoy. But who shall excuse the hireling who, in the interests of electric-lights, climbs our trees with spiked shoes that tear holes in the bark, hews away great limbs, leaving the stumps to absorb moisture and decay into the very heart of the old Elm or Maple, or, worse still, places his wire so carelessly that it is found burning the boughs away, so that they fall with a crash, to the peril of the incautious foot-passenger.

From such depredations as these it seems as if there must be some legal defense. It is useless to remonstrate with the men with anything gentler than a shot-gun, and it seems sometimes as if its use upon such wanton trespassers would be almost justifiable, so insolent and unheeding do they become in their irresponsible onslaughts upon private property.

Sooner or later there must be some legal issue made upon this matter if we are to preserve from mutilation and destruction our fine avenues of trees which now suffer at the hands of these electric depredators, who certainly have no authority for wholesale damage to the trees which may interfere with their lines. It would be well enough if they and the Road Commission would show their zeal in the destruction of such trees as are breeding-places of black-knot and other diseases, or which harbor

the curculio. Herbaceous plants, too, which are pestilent weeds, and spread by seed into adjacent fields, ought to be destroyed. But no discrimination is made. Lilies and Columbines and Clematis fall with the Canada Thistle, and a warty Wild Cherry is quite as safe as a Tulip Poplar. If half the zeal were displayed in a persistent warfare against the real pests of forest and farm as is now exercised against the beautiful growth along country way-sides, injurious insects and infectious fungi would soon be less abundant and destructive.

Botanical Nomenclature.

WE have received a circular containing the suggestions of a committee composed of the following well-known German botanists, Ascherson, Engler, Schumann and Urban, appointed to amend the laws of botanical nomenclature as adopted at the Paris Conference of 1867. The committee proposes the following changes:

First, that the starting-point of the priority of genera, as well as species, shall be 1753, the date of the publication of the first edition of Linnæus' *Species*, instead of 1737, the date of the publication of the first edition of his *Genera*.

Secondly, that nomina nuda and seminuda shall be rejected, pictures alone without diagnoses not being allowed any claim of priority.

Thirdly, that similar names shall be preserved if they differ by ever so little in the last syllable, although if they only differ in the mode of spelling the newer one is to be abandoned.

Fourthly, the names of certain large and universally known genera, a list of which is added to the report, are to be preserved, although if the strict rules of priority were followed they would be rejected.

The committee states, as a reason for abandoning the first edition of the *Genera* of Linnæus as the authority for genera, that "the turning-point from the ancient botany to our modern science rests in the introduction of the binomial nomenclature, as previously to the publication of the *Species Plantarum* (1753), which followed a year after the fourth edition of the *Genera*, the scientific position of Linnæus was not superior to that of Tournefort, Rivinus and many other botanists who often had described and segregated the genera more exactly than he did."

With reference to their second change the committee say: "Many genera have been founded on a picture only without a diagnosis. No doubt, by means of it a species sometimes can clearly be made out and recognized, and if the picture is a good one all the characteristics of the plant can be observed. But a picture can never show the special characteristics alone which raise the genus above the other of its affinity. A genus only gains priority by a verbal diagnosis, and nomina nuda and seminuda are to be rejected; therefore the following works cannot claim a right of priority: Rumphius, *Herbarium Amboinense*, Burmann, *Flora Indica*, Patrick Browne, *History of Jamaica*, Lamarck, *Illustration des genres pro parte*, etc."

As illustrating the meaning of Article iii. the committee would preserve *Adenia* as well as *Adenium*, *Chloris* as well as *Chloræa* and *Chlora*, *Atropa* as well as *Atropis*, while such cases as *Epidendrum* and *Epidendron*, *Oxycoccus* and *Oxycoccos*, are held to be only different modes of spelling the same word, and the newer one is to be abandoned if they relate to different genera.

The provisions of Article iv., as proposed, are more radical, and will give rise, probably, to more criticism than the others. In their explanatory note the committee state that "the impulse that led to the acknowledgment of the right of priority was only the vivid desire to create a stable nomenclature. If we see that by the absolute and unlimited observance of the principle we probably gain the contrary of what we intended; we, who have ourselves made the rules of priority as a law, have the right to amend the latter. Therefore we present a list of genera that have more than a merely scientific interest or that are very large,

and we propose to conserve them in spite of the rules of priority, in order to avoid a general confusion by the change of many thousand names." They then give a list of seventy-eight genera for which they would propose to preserve names which are not the oldest. Among these some of the most interesting to American botanists are *Malvastrum* (1849) in place of *Malveopsis* (1844), *Oxytropis* (1812) for *Spiesia* (1790), *Desmodium* (1813) for *Meibomia* (1763), *Liatris* (1791) for *Laciniaria* (1762), *Mikania* (1803) for *Willoughbya* (1790), *Statice* (1807) for *Limonium* (1759), *Dendrobium* (1799) for *Callista* (1790).

The first article seems to us unimportant, although, as all modern nomenclature rests upon the system of Linnæus and dates from the publication of his *Genera* and *Species*, we should prefer to go back to the first edition of the *Genera*, although it was published before his binomial system was perfected and before he had established his supremacy over all his rivals.

Of the wisdom of the second clause there can be no question, as no theory of nomenclature can stand which is based only on the use of names unsupported by published diagnoses, although we confess we do not understand the wisdom of excluding Browne's *History of Jamaica*, as his diagnostic characters supported by figures rarely leave any doubt as to the species or wish to record.

Article iii. will certainly be approved by working naturalists; but whether the great majority of these adopt the fourth article and consent to an arbitrary selection of certain names, these names being taken contrary to a well-established rule and simply for convenience, seems to us doubtful. If all naturalists could be induced to agree to call *Malveopsis* *Malvastrum* or *Spiesia* *Oxytropis*, because these names are more familiar to the present generation and their retention would save labor and confusion, and if not only the present generation of naturalists, but their successors for all time, could be bound to adopt these names, then the plan would be an admirable one. But, unfortunately, the only way to make nomenclature really stable is by an unflinching adherence to a rule. If one exception is admitted another will be, and as long as the human mind is active there will be botanists who will think that they can secure notoriety for themselves by changing names and by making other deviations. To prevent this and to make nomenclature stable, it seems to us that the law of priority must be maintained at any cost of labor and inconvenience, and that the longer its adoption is postponed by makeshifts like the one here suggested and by efforts to avoid meeting the issue squarely, the greater will be the ultimate confusion, and we deplore any effort to postpone changes of names which, sooner or later, are sure to be made, and every attempt to avoid compliance with the fundamental law on which scientific nomenclature is based.

The whole subject, however, is one which demands careful consideration and discussion as well as the co-operation of working naturalists in all parts of the world; and their contemporaries will be grateful, whether they agree with their recommendations or not, for the thought and labor the members of this committee have bestowed upon this most difficult and perplexing subject.

The New Jersey Building at the Columbian Fair.

FOLLOWING the example set at the Philadelphia Centennial, the various states of the Union will have houses of their own on the grounds of the Columbian Exposition at Chicago. Of course, the attractiveness of the portion of the grounds devoted to these buildings will depend on the taste shown in their design. The most prominent of all these structures, the one belonging to the state of Illinois, does not seem to us worthy of the fine position it occupies, while the New York State building, which is to be in the style of an Italian villa, seems very appropriate to the use for which it is intended, and, judging from drawings, it will be a work of great beauty. The

commissioners for New Jersey have done wisely in selecting as the model of their club-house the old Washington Headquarters at Morristown, which is the most famous house in the state and one of the most famous historical houses in the Union, not only because more persons distinguished in the military history of the Revolution have been gathered under its roof than under any other roof in America, but because it is an excellent example of the architecture of the time when it was built, and because it has been kept in such an admirable state of preservation. It is rather unusual, too, in America, for a house to remain continuously in the possession of one family so long as this one did, for the deed which conveyed the building to the trustees of the state was given by the seventh generation, counting from the honored mother of Colonel Jacob Ford, who owned the building when it was occupied by Washington.

The original house seems good for another hundred years at least, and the same oaken planks, caulked like the shell of a frigate, remain on the outer walls as sound to-day as when they sheltered Washington from the storms of the winter of 1779 and 1780. The old floors are still firm; the double oaken doors, which opened and shut for Washington, open and shut to-day, and there has been hardly any change or repair or restoration in the house from bottom to top. The same surbases, windows, mantel-pieces, fire-places, hearth-stones, and the same carving on the lintel and cornice remain just as they came from the hands of the artisan. The house, too, with its wide hall and spacious rooms, will be cool and well adapted to the purpose for which it is intended. Let us hope that all the details of the building will be accurately copied, so that it will be a genuine reproduction and not a parody. Of course, one thing cannot be repeated, and that is the surroundings of the old house at Morristown. One charm of the place is the perfect adaptation of the house to the rich landscapes which stretch away from it on every hand. One change is said to be contemplated, but this will not be ruinous, and that is the addition of an extension similar to the one seen in the right of the picture, on page 367, on the opposite end of the house. This would be after the symmetrical style of southern colonial houses, and would, probably, be what Colonel Ford would have done if he had ever enlarged his residence. Nevertheless, if the building, as it now is, offers room enough for the accommodation of New Jersey at the fair, no change whatever in the model should be permitted.

Water-plants in Southern New Jersey.

VERY attractive are the ponds in the Pines at this season, with the plants which float upon their surfaces or bloom above them or riot in the swampy ground about their margins. The sweet-scented Water-lily (*Nymphæa odorata*), with its singular grace of form, purity of color and exquisite fragrance, must ever remain the queen of wild water-flowers. These plants are attractive anywhere, but they are never so charming as they are in some lonely wood-bordered lakelet. No doubt, the cultivators who make artificial basins for growing them enjoy their loneliness, and this is the only way most people are permitted to enjoy them. But a Tank-lily can never be a Pond-lily, after all. Varying forms of the yellow Pond-lily (*Nuphar*) are here, too, some with yellow flowers, others quite purple. The flower is interesting and curious, with its many-rayed stigma and numerous small petals crowded among the stamens under the ovary, a snug retreat, where small insects seem to find something to their liking.

Another plant belonging to the Water-lily family is the peculiar *Brasenia peltata*, or Water-shield, which is scattered in thick patches over the ponds. Its long-stemmed, shield-shaped leaves float gracefully on the water and bear clusters of small purple flowers in their axils. The stems and flower-buds are coated with a clear, limpid jelly, and when held in the sunlight they sparkle like plants covered with ice after a winter's sleet. The Floating Heart (*Limnathemum lacunosum*) is another plant quite common in the ponds. It has smooth, shining, small heart-shaped leaves, often beautifully

mottled with white, and pretty clusters of small white flowers. It belongs to the Gentian family, and continues in bloom throughout the summer. The large velvety leaves of the Golden-club (*Orontium aquaticum*) are also floating on the water, and the greenish-looking seeds are falling from the spadix and scattered along the edge of the pond.

The narrow-leaved Cat-tail, *Typha angustifolia*, as well as the more common *T. latifolia*, left its spears above the marshes in a delightfully decorative way. The narrow-leaved *Typha* is specially pretty and delicate, with its slender, dense, brown spikes of flowers. And *Sagittaria*, with its many forms, well named from its arrow-shaped leaves, is not to be despised. The flowers are pure white, and some of them are quite large and handsome, although they look so frail, with their almost transparent petals. They keep in bloom all summer long. The blue flowers of the Pickerel-weed (*Pontederia cordata*) contrast well with the *Sagittaria*, and were it not for the ephemeral character of the flowers, which gives the spike a ragged appearance, they would look charmingly together, as they both continue in bloom well into October.

The button-like dull white flowers of *Eriocaulon*, or Pipe-wort, stand well up out of the water on their straight, slender, naked scapes, while their loose, cellular, grass-like leaves are entirely submerged. Two or three species of Yellow-eyed Grass (*Xyris*) are in company with *Eriocaulon*. The slender, rigid, compact leaves and scapes of the first are quite in contrast with the loose cellular structure of the other. The flowers of *Xyris* are small and yellow, and produced all summer from rigid scale-like heads. The leaves and scapes of some of the species are curiously contorted and twisted, especially in those of *X. torta*.

Several species of the perplexing Bladderwort (*Utricularia*) are floating on the water, eluding all of my efforts to learn the cause of the merciless slaughter of the little aquatic animals around them. *U. clandestina*, perhaps, causes more ruin among the tiny inhabitants of the pond than either of the other species. Its submerged leaves and stems are thickly studded with curious bladder-like traps, ready to capture the unwary creatures which venture near enough to touch the marvelous door which suddenly opens and draws them in and quickly closes, never to be opened from the inside to let a victim escape. Great numbers of the larvæ of the chironomus-fly and of the mosquito, and many entomoscans are alike made prisoners in their chambers of death.

The inflated Bladderwort (*U. inflata*) is the most elegant species in the genus. It floats on the water easily and gracefully at the will of the wind, with erect stems surmounted with large yellow flowers. In the place of roots is a whorl of white inflated bladder-like stems, each an inch or two in length, which keep the plant afloat and right side up. Below the inflated stems are finely dissected leaves containing many little bladders with the same structure as those of *U. clandestina*, but, as far as I have observed, this species entraps very few creatures. Another handsome species is the Purple Bladderwort (*U. purpurea*). This also floats on the water, but in thick tangled masses, from which arise many flower-scapes with rather large purple blossoms. This species bears more bladders than either of the others, and under a low power of the microscope they are beautiful objects. Their construction is quite unlike those which belong to the yellow-flowering species.

Great masses of *Drosera longifolia* are growing in the more shallow places, with long stems raising the leaves and flowers out of the water. In some places they are as thick as they can well stand over quite a large space. They are beautiful plants glistening in the sunshine like jewels. But they, too, are death-traps, and destroy the lives of many creatures of the air, that seem to be attracted by sticky fluid that exudes from the glands and sparkles on their leaves. When a fly alights upon a leaf it is held fast, and many of the leaves are found folded entirely around their victims.

Another species, *D. filiformis*, is here too, growing in wet sand; this has long, thread-like leaves, ten to twelve inches in length, covered from base to summit with reddish glands like those of *D. longifolia*. The scape is a foot or so in height, bearing handsome rose-colored flowers which last through July and August. This species captures many insects, butterflies and moths and large *Asilus* flies, and many others. When an insect alights and finds itself fast, it is natural for it to reach out and grasp other leaves, and so it becomes more and more entangled among them, until escape is impossible. The handsome Pitcher-plant also grows here, and looking within its curiously constructed cup we find here, too, many captured insects.

Vineland, N. J.

Mary Treat.

Notes on the Flora of Smythe County, Virginia.—I.

THE mountains of south-western Virginia have been so often and so thoroughly explored and botanized over that it would seem that nothing new could be found there, and that anything written about their flora would be an altogether too oft-told tale. The reality was, however, always fresh, and every new excursion through sometimes almost untrodden forests and up to mountain-summits reveal, if not new plants, at least those that, either by their beauty, great luxuriance or curious structure, never failed to interest the collector. Marion, in the neighborhood of which most of our botanizing was done, lies in the heart of Smythe County, on the Middle Fork of the Holston River, about twenty-eight miles, as the crow flies, from the boundary-line of North Carolina. It is a small straggling village on a slope at an altitude, they say, of 2,300 feet, surrounded in every direction by innumerable little foot-hills, called by the natives knobs. Most curious little hills they are, molded and furrowed and worn into all sorts of whimsical shapes. There are round hills, pointed hills, symmetrical hills; hills that have gentle slopes, hills that are too steep for the most ambitious tobogganist, and hills that have no shape whatever. Beyond them to the south, in the Blue Ridge, rises the long, scarcely broken range of the Iron Mountain, and still beyond, in the same system, the two high peaks, White-top and Mount Roger, the latter familiarly known as Balsam Mountain, for the names of the United States Topographical Survey maps are not by any means the local names. North of Marion the long, straight, almost plateau-like level of Walker Mountain completely shuts out any view into the broad valley of the North Fork of the Holston River beyond. All the mountain-tops are densely wooded, with small scattered farms with Rye and Corn fields on the lower ridges, and in the fertile valleys many an acre of rippling Wheat-fields.

The Holston at Marion is rather more than a brook, something less than a river, and it flows between high banks that gradually, a mile or so below the village, become so steep and rocky as to make it practically inaccessible except at certain intervals. The river tosses and foams between Moss and Fern fringed cliffs and dense and fragrant woods of *Arborvitæ* and Hemlock. The latter were all large, fine trees, and the *Arborvitæ* giants of their race. One of the largest of the latter measured nearly fifteen feet in circumference, and many were more than half that size. For a month or more we botanized at intervals along the river-banks, and the succession of plants was most interesting.

Toward the latter part of May the flowering trees and shrubs were numerous. Some superb Wild Black Cherry-trees were in bloom in the woods and along the roads. Many of them were large trees, and were beautiful objects while their flowers lasted. Redbud was in its glory, and both Dogwoods, *Cornus florida* and *C. alternifolia*, were in bloom at the same time, and side by side in great clumps. The Sugar-berry (*Celtis occidentalis*) was just dropping its flowers, but the pretty Bladder-nut (*Staphylea trifolia*) was still hanging out its graceful, drooping white bells. Rather smaller than this was the Nine-bark (*Physocarpus opulifolius*), a most effective *Spiræa*-like shrub, and *Barberis Canadensis*. The Barberry we found was fairly widespread all through the county on dry hill-sides as well as on the river-banks, though nowhere in any great quantity. Its yellow drooping racemes are very pretty, and altogether it is a neat little shrub. The clefts of every rocky ridge were filled with great bunches of *Hepatica acutiloba*, then in fruit, and quite close to the village one of the cliffs was covered with a mass of *Polypodium incanum* growing on the edge of and in the seams of the rocks. With it were the Cliff-brake (*Peltæa atropurpurea*), a light green, somewhat silvery-looking, Fern, and two *Aspleniums* (*A. parvulum* and *A. Rutamuraria*), the latter with fronds nearly three inches long. At the base of the rocks and through the woods was the pretty *Oxalis recurva*. It is a handsome plant, quite erect, and over a foot tall, the golden yellow flowers being in many instances nearly an inch across, and the leaves very striking, with their bright brown margins. In the swampy borders of the river *Phacelia Purshii* was abundant, a beautiful species, with a rather straggling habit and delicate light blue-fringed corollas.

Violets have a more or less prominent place everywhere during the month of May, and in the vicinity of Marion their profusion and luxuriance of growth was most surprising. In all we collected thirteen species in the valley and on the hills, all, with the exception of the little yellow one, *Viola rotundifolia*, blooming at the same time. With the *Phacelia* on the river-bank was *Viola striata*, over a foot tall, with large creamy white flowers, and *V. rostrata*, smaller, with flowers of two

shades of lilac-purple. The latter was by no means rare, and could be seen all through the swampy woods and often in open fields, where it did not reach three inches in height. The near relative of the Violets, *Solea concolor*, a coarse herb with inconspicuous little greenish flowers, grew with the white Violet on the river-bank.

The only Iris we found in the region was *I. cristata*, a lovely light bluish flower with yellow crests, on wooded hill-sides, growing in great beds. Many of the shrubs were overgrown with an impassable tangle of Cat-briers, prominent among which was *Smilax hispida*. *Dioscorea villosa* and *Smilax herbacea* were in such close proximity that it was hard to say where one ended and the other began. The curious Leather-flower (*Clematis Viorna*) was found trailing on hot, dry hill-sides on the ground, the flowers standing up straight from the vines. They are more than an inch long and of a delicate reddish purple. One of the most striking among the smaller plants on the river-bank was the light violet-blue *Cedronella cordata*. Higher in the mountains and in more sheltered situations its flowers were of a delicate pink. During the last week in May, as soon as the Red-bud flowers were over, the Locusts (*Robinia Pseudacacia*) began to bloom, and lasted in the valleys for over ten days. The village streets and the fields and woods were full of their sweet fragrance. In the deepest and gloomiest part of the Holston ravine grew the Twin-leaf (*Jeffersonia diphylla*). It was in fruit when we found it, but was none the less interesting, as the pear-shaped pod with its little cone-shaped lid and bright orange-brown seeds was very quaint. The Barren Strawberry (*Waldsteinia fragarioides*) was found in a little isolated bed under one of the big Hemlocks, and with it was the bright rose-purple *Polygala pauciflora*, a charming little plant, by no means uncommon in the mountain-region.

Great cliffs were covered with long pendent masses of the Bladder Fern (*Cystopteris bulbifera*), and some of the rocks were so covered with mats of the Walking-leaf (*Camptosorus rhizophyllus*) as to be completely hidden.

In a shady nook was quite a dense growth of the plants of *Aconitum uncinatum*, and with them the straggling *Polemonium reptans*, with blue-purple nodding flowers. *Spiranthes latifolia*, the prettiest of the North American Ladies' Tresses, was growing on the edge of the water, almost in the river, and near it the queer little green spike of another Orchid, *Habenaria bracteata*. The Leatherwood and the Spice-bush (*Lindera Benzoin*) were both beginning to fruit in the densest portion of the wood, and the silky Cornel or Kinnikinnick (*Cornus sericea*) was just opening its flowers on a little island in the river.

New or Little-known Plants.

Richea pandanifolia.

THIS very remarkable Tasmanian plant, of which living examples are now in cultivation at Kew, is figured and described in Hooker's *Flora of Tasmania*, where it is said to grow in the dense mountain forests in the interior of the southern and western parts of the colony, presenting a more striking appearance than any other Tasmanian plant, its long, naked, slender annulate stems attaining a height of thirty-six feet, and bearing one or several huge crowns of long waving leaves, often rising far above the surrounding vegetation, and strikingly resembling in general aspect the mountain Pandani of India. The trunk is nine inches in diameter, with a large pith, sometimes branching with a crowded head of rigid coriaceous leaves, each from three to five feet long, shining green sheathing at the base, tapering to a long point, the margins finely serrated. The flowers, which are small, are produced on a compound axillary panicle six inches long. The appearance of the plant certainly suggests an endogen, such as *Bromelia* or *Pandanus*, rather than the exogenous order *Epacridaceæ*, to which *Richea* really belongs, its nearest affinity being the well-known genera *Sprengelia* and *Dracophyllum*. The Kew plants were raised from seeds collected by Mr. Justice Dobson, of Hobart, in 1882, from whose letter to Sir Joseph Hooker I am permitted to make the following extract relating to the *Richea*. He wrote: "To get these seeds I made an expedition to the head of the Lachlan River, which falls into the Derwent,

close by New Norfolk. The only route is up the bed of the Lachlan. The sides of the hills are most precipitous, and the bed of the river is a mass of dead timber, rocks, boulders, waterfalls and everything else that can make traveling difficult. After ascending 2,500 feet we got to

seed. Sphagnum grew abundantly about these giants, who seem to love plenty of moisture at their roots and to enjoy a rotten, peaty soil."

The Kew examples of *R. pandanifolia*, which are now ten years old (see illustration on this page), are two feet high

Fig. 61.—*Richea pandanifolia*.—See page 364.

the top of the tier, a marshy, scrubby plateau, where, after struggling through *Baueria*, *Fagus Cunninghamii*, *Leptospermum* and cutting grass, I saw the first giant *Richea*. There were about forty trees, and most of them were in flower, but as the old flower-stalks and seed-vessels continue adherent to the tree, I succeeded in finding good

and have leaves nearly two feet long. Judging by the behavior of these plants, a full-grown specimen must be many years old. They are evidently not difficult to manage in cultivation, and so far they have proved just as happy in a hot moist stove as in an airy greenhouse. They grow well in sandy peat, and like a liberal supply of

water at all times. Apart from their exceptional botanical interest, they are quite as ornamental in appearance as some Pandani and Cordylines.

There are eighteen species of *Richea*, all natives of the mountains of Tasmania and south-eastern Australia. Some of them are small and bush-like, with leaves only an inch or so in length. *R. dracophylla* grows to a height of twelve feet, and has flexuose leaves two feet long. I am not aware that any other species of *Richea* is in cultivation in Europe except the one here figured, with the introduction of which Kew is to be credited.

Foreign Correspondence.

London Parks.

EVERY year more open spaces are provided in England for pleasure-grounds, and those most recently acquired are largely planted with hardy flowers in bold groups or with masses of annuals which are in their respective seasons gay with color. The shrubs in these places, however, are not so satisfactory. They are mostly crowded together so that they die from strangulation or starvation, or at least they make no characteristic or healthy growth. Horticulturists fond of brilliant effects will be pleased with the bedding in Hyde Park, from Rotten Row to the Marble Arch, the ground running along the Park Lane being now a blaze of Fuchsias particularly, although other flowers, such as Tuberous Begonias, are used freely.

For a few years past the Fuchsia has been a great favorite here for bedding, and in such large masses as can be seen in Hyde Park the effect is most pleasing. For the most part the fine old-fashioned kinds that have been almost lost sight of since the flower has been out of fashion are to be seen in the public parks. One of the most popular kinds is the Earl of Beaconsfield, the flowers of which are tubular and scarlet. Other varieties preferred are Annette, distinguished for its massive green leaves and purple-crimson flowers, the Empress of Germany, with violet, blue and crimson flowers, Tower of London, Madame Cornellesin and Elizabeth Marshall. The plants are about three feet high and are grouped in threes, usually of distinct kinds, on the turf, so that the lower shoots touch the closely trimmed grass and the little shrubs are each one a pyramid of bloom. The great point in dealing with such tender plants as the Fuchsia is to let them make as much of their growth as possible in the open air so that they become thoroughly well-hardened to endure the trials of summer weather and maintain a display of flowers until frost.

Of course, in large places, size counts for something, and besides the large specimens of Fuchsias are admirable groups of *Erythrina Crista-galli*, *Pelargonium*, *Madame Crousse*, a fine ivy-leaved variety with salmon-pink flowers, and *Clematis Jackmanni*. The Tuberous Begonia has done much to displace the beds of *Pelargoniums* in the English parks. As far as possible the colors are kept distinct so as to gain a full and strong effect. It is possible now to purchase seeds in distinct shades, and they produce flowers true to these tones, while in regard to size and habit there has been a great advance in the outdoor Begonias, whose flowers have great breadth, stand well up above the foliage and seem to be proof against the vicissitudes of weather. A moist season suits them best, and while the *Pelargoniums* have run to leaf the Begonias have been smothered with bloom.

The tufted Pansy is another plant much used in the parks as an edging, as a groundwork to taller things, and in beds by itself. The important point with these is to select varieties of good color, and there is no kind more generally used than Archie Grant, which has bold flowers of deep royal blue, which never lose their character throughout the year. These Pansies are a charming group, which now range through many colors, from white to the deepest

purple. They commence to bloom in spring and continue to the end of summer, disliking only severe drought.

It is surprising what may be accomplished in outdoor gardening even in London, one of the smokiest cities of the world. One of the most successful plants used here is the Carnation, which is planted very freely. The old Clove succeeds remarkably well, and forms large clumps. Americans when visiting England should not forget the parks and city gardens, which are worth seeing all the year. In the spring months the bulbous flowers are used freely. Last spring the beds now occupied by the Fuchsias in Hyde Park were filled with the best kind of Daffodils—that is, those with the earliest flowers, like the Maximus, Horsfieldi or Empress type, while the Poet's Narcissus followed later in the season.

Chiswick, England.

Cultural Department.

August in the Vegetable-garden.

THOSE who enjoy a sweet, quickly grown turnip should sow now a few of the Extra Early Milan. I say a few, because those sown now will be overgrown and pithy before cold weather, and successive crops should be sown to follow the first. Here, in the south, we can sow this variety as late as October and grow a fine crop, the last sown usually being best of all. The Extra Early Milan grows almost as quickly as a Radish, and when the size of an ordinary biscuit is a delicious table-turnip; but sowings should be continued to have it in the best condition, and in the latitude of New York seed can be sown in rich ground as late as early September. For a turnip to keep in winter, we like the variety known here as Southern Prize. It is not catalogued by northern seedsmen, but can be had of seedsmen from Richmond southward. Robertson's Golden Bull is another good variety for winter use. Both of these require a longer season than the strap-leaf sorts like the Milan, and should be sowed at once.

In the latitude of New York the winter crop of Celery is now in its final quarters, and the only thing to do is to keep it free from weeds. Do not handle or cultivate Celery when wet with dew or rain.

Plants of Brussels Sprouts can be set now in the latitude of New York in moist and rich land. This vegetable is too rarely grown in this country, partly, I suppose, because it will not stand out in the north, and it is not in good condition until touched by frost. But Brussels Sprouts may be stored like Cabbage, and in the south they ought to supplant the coarser Collard, for here they can be left to stand during the winter. If our northern friends, for any reason, have failed to set their winter Cabbage-plants at the proper time for them—in early July—let them get now, if possible, plants of the Winningstadt Cabbage, and they will still make good heads.

In most localities seed of the Barletta, or the Queen Onion, sown early in August, will make a fine crop of beautiful little pickling onions. In the south, the main garden crop of August is the late Potato-crop from seed of the early crop. We bed our early potatoes in the open ground and cover lightly as soon as dug, and in August take up and plant those that are sprouted, and no others. This crop is becoming of great importance in the south, as we find that these late potatoes are vastly superior for spring planting to any we can buy at the north, and, from the fact that they can be kept unshriveled until July, they will be of great value as a food-crop in late spring. Northern gardeners are now finding it to their advantage to get these late-grown potatoes for planting them in spring, and quite a trade is springing up in seed-potatoes from the south.

Broccoli, for fall use, should now be set in northern localities, where it does well. This is Cauliflower under another name, and usually takes the place of Cauliflower in autumn. About Baltimore the gardeners call the green-curled Scotch Kale Broccoli, and they set it out at this season just as they do late Cabbage. It makes a fine vegetable after frost, and is so hardy that it can be left out almost anywhere. When grown in this way it is much better than that sown later and cut small for "greens."

Try a crop of Peas early in August. Sow them in a trench and cover lightly, and work the soil into them as they grow. If they escape the mildew, they will give a very acceptable autumn dish. The best sorts to sow now are Premium Gem and Chelsea. A dusting with flowers of sulphur is good as a preventive of mildew.

If Carrots are relished in winter, sow now some seed of

Early Horn variety. They grow quickly. Eclipse Beets sown now will be better for winter use than the long ones usually sown earlier.

Late in the month of August sow seed of Chinese Rose-colored Winter Radish. We have tested all the varieties of winter Radish, and are of the opinion that this is the only one worth growing. Successive sowings should be made into September, as the first may grow pithy. Here we can sow them until middle of October.

From Maryland southward long cuttings of Sweet-potato vines made early in August, say a yard long, and wrapped in a coil, putting the whole in a well-watered hill except the tip, will make a great crop of small tubers, which will keep better in winter than the potatoes from the spring setting, and make the best seed for next spring's bedding. In the Carolinas and southward the best potatoes for winter table use are grown from these cuttings.

Raleigh, N. C.

W. F. Massey.

The winter made matters worse; and now our bushes are practically old and worn out, instead of being virile and young.

The remedy must, of course, be suited to the disease. Our fields must be arranged to defy drought as far as possible. This can be done by thorough cultivation in the spring, by mulching, and by growing the canes five feet or more in height, thus shading the soil more effectually between. But it is not impossible or seriously expensive for many of us to arrange a system of irrigation. In any event, there must be a prompt removal of fall blossoms, if these are abundant. The canes must in no way be devitalized before winter—that is, we must get strong canes, and keep them strong. I have never seen poorer than those prepared in 1891 for 1892; and the result is an inferior crop. Of course, a good deal can be done by high manuring. It must also be borne in mind that different varieties of berries demand different methods of culture. The Turner must be grown in hills, to give any fruit worth mentioning; while the Cuthbert does best when grown in

Fig. 62.—Washington Headquarters, at Morristown, New Jersey.—See page 362.

The Raspberry Crop.

THE Raspberry crop of 1892, after all, is a failure. The fruit is inferior, and the quantity produced about one-fifth what it should have been. The case is one full of interest and worthy of study by horticulturists. If the fruit as brought into market is examined, it will be seen that it is rusty or has a whitish appearance. The berries are not filled out well, and are not large or succulent. At the opening of the season the bearing canes looked as exhausted as they generally do near the close of the picking season. In the spring these canes were found to be killed back one-third, and were enfeebled. The severity of the winter was not enough to account for this. The second crop, borne last October, was my first reason for the exhausted bushes. But, perhaps, the cause lies still further back. The year 1891 was extraordinarily dry in the growing season. The canes were few, and short and slim. The lack of vitality and badly formed cells led to an effort to bear fruit, exactly as girdling an Apple-tree makes it at once a bountiful bearer. So our weak canes pushed out an autumn crop, a useless fruitage. This still further weakened them.

close rows with tops interlocking, and the whole ground shaded. What is true of the raspberry crop is also true of most other fruits, when the prolonged dry weather of last year was most marked. The cherry and plum crops fail, and pears, while blossoming profusely, have not set fruit. This result may occur from numerous causes, but I am confident, from examination, that the chief cause for the failure this year is the enfeebled growth of last year. It is agreeable to look forward to 1893 with a certainty that fruit will be admirably provided for, so far as abundant and vigorous growth is concerned. The Raspberry-canecan are abundant and are strong. Such growth will not encourage premature fruit-bearing in the fall.

Clinton, N. Y.

E. P. Powell.

Notes on Shrubs.

DURING the last two weeks, or the second and third weeks in July, the objects of most comment and greatest popular interest and admiration by visitors to Franklin Park, in Boston, have been the knolls, banks and other bits of ground covered with dense masses of *Rosa Wichuraiana* in full bloom.

At a little distance the ground sometimes seemed so thickly covered with the white flowers as to almost give the effect of snow, while a nearer view showed innumerable clusters of single white Roses of good size with yellow stamens, and well set off by a thick covering of handsome immaculate dark green foliage over the ground beneath. The fragrance given off is not that of most wild Roses, but more nearly suggests the Banksian Rose of our greenhouses, although it is sweeter and without a certain disagreeable quality of the Banksian. Bees of various kinds, but especially honey-bees, were present in large numbers about the abundant bloom.

In the two or three years since it has been planted in this park, *R. Wichuraiana* has shown a wonderful capacity for growth and for covering the ground almost to the complete exclusion of any other form of low-growing vegetation. It has been planted in Franklin Park in various situations—among other shrubbery, by itself in masses, on knolls and on rocky banks—and in any of these situations it appears to thrive equally well. In some places where it was planted with double-flowering Blackberries, dwarf *Spiræas* and similar plants, its rampant stems have largely overgrown them, so that they seem to be fast getting crowded out. Some *Rhododendrons*, planted in an inappropriate and artificial situation, are becoming partly hidden in the wild growth of this Rose, which was planted as a ground covering beneath. As a rule, the stems of the Rose trail closely along the ground, but the new stems of each succeeding year grow over the preceding ones, and where the tips get a chance to climb through the branches of some other shrub they take advantage of the support and become more or less raised. In fact, its habit is more like that of a trailing Blackberry or Dewberry than any other familiar object. Considering that its importation was undesigned or without a knowledge of its peculiar habit or value, the introduction of this Rose has proved a very fortunate circumstance. Its dark, shining, evergreen-looking foliage will form a splendid covering for any rough piece of ground, and sandy or gravelly areas are likely to prove very congenial to the growth of the plant. It is now (July 26th) still in good showy bloom, but a week or ten days ago was in its very best condition.

Our own Michigan or Prairie Rose (*R. setigera*) is the contemporary of *R. Wichuraiana* in its season of blooming, but its direct opposite in the color of its abundant deep rose-colored flowers, which form a most striking contrast and make a bold show. Left to grow in its own natural way, the stems of this Rose will climb twelve or fifteen feet or more among the branches of other shrubbery and small trees, but if it is planted alone and has opportunity to develop on all sides the stems will rise for three or four feet and then arch and bend over, with the tips trailing on the ground, and the whole will appear like a little mound profusely covered with large clusters of nearly scentless flowers, which are usually in finest condition from the 15th to the 20th of July. It is perfectly hardy here, and, considering that it is a plant long in cultivation, it is surprising to find it still comparatively a rarity in gardens, and it is even unknown to many gardeners and professional nurserymen. It has not been known to produce seed in this region, so that it is necessary to propagate it by cuttings or other modes of division. Cuttings of half-ripe wood taken at the end of August root without difficulty. The foliage is large and ample, and bears a distant resemblance to some members of the Raspberry tribe or genus *Rubus*. One of the synonyms given to it by a botanist was *Rosa rubifolia*, and under this name it is still sometimes to be found in catalogues.

Our native *R. Carolina* forms the third in this group of useful late-flowering single Roses, for these three are the only hardy species yet introduced which bear flowers as late as or later than the middle of July. A few flowers on each of them may be found as late as the 1st of August. *R. Carolina* is the only one of the three which has an upright bush-like habit. Its flowers are smaller than and not so conspicuously showy as the others, and they are produced in less simultaneous profusion, but they are the late Wild Roses of our own way-sides, and, as they possess a sweet wild-rose fragrance, they are always sure of a place in popular esteem. A single plant will gradually spread by underground shoots until, in a few years, it will form a large clump.

Along the cool sea-coast north of Boston such Wild Roses as *R. lucida* sometimes continue blooming until the middle of July, and in such places the *R. Carolina* is proportionally late. Such Roses as these are the species which should be planted about a sea-shore home, as being most natural and appropriate, and, at the same time, quite hardy and able to withstand the rigor of winter without unusual care.

Arnold Arboretum.

Rose Notes.

EARLY-planted Roses for winter flowering will now be benefited by a thin mulching of manure, but it is safer to err on the side of thinness than to apply too heavy a coating, as the latter frequently results in injury to the plants. The use of a moderate quantity of bone-dust is at all times beneficial to the soil for Roses, providing the bone be of good quality, and the most satisfactory grade of this fertilizer that I have used is that secured from a button factory, because the bone so used is in its natural state, and is much superior as a plant-food to that which has been boiled or dissolved with acids. Good bone-dust feels somewhat greasy when rubbed between the fingers, while that prepared from bones that have been boiled in order to extract the oil is quite dry, and feels gritty to the touch.

As the young Roses make their growth, disbudding must be attended to frequently, for the strength of the plant is all needed to make wood at this season, so as to secure a strong growth ready for winter flowering; and even in winter it is necessary to disbud regularly if flowers of extra size are desired. This is practiced by the large commercial growers who make a specialty of Roses, and they disbud as regularly as they do in the case of *Chrysanthemums*, in order to produce the eight and ten inch flowers frequently seen at the autumn shows. Among the varieties specially benefited by disbudding are the *Bride*, *Catherine Mermet* and *Wooton*, all of which send out lateral buds before the terminal flower opens, and thereby its size is reduced. *La France* is also improved by the same method, for this variety, when growing strongly, often forms lateral buds.

The young Roses should, of course, be staked before the new growth proceeds very far, not only for neatness sake, but also for the welfare of the plants, and it may be worth repeating that the most satisfactory method of staking is by means of a piece of galvanized steel wire about the thickness of a lead-pencil and three to four feet long. This is secured in an upright position by means of a longitudinal wire stretched between supports at each end of the bed. Wire of this character will last for several years, and is not nearly so obtrusive a support as is a wooden stake.

If some space has been devoted to hybrids planted out for winter forcing the plants should now be in active growth, and they will need an abundance of air and water, though, at the same time, the effects of sudden changes of weather must be guarded against to avoid mildew. The main object now is to secure a strong, clean growth. In establishments where space for Rose-growing is limited, it is preferable to prepare hybrids for winter use in pots, as they can then be stored in a cold frame until needed, but it must be conceded that the pot-grown plants seldom produce as fine flowers as those that have been planted out.

The present has not been a satisfactory season for outdoor Roses in this locality. The weather has been too dry, and, as a natural result, the flowers have been small and not lasting. Teas that were planted out for summer flowers have been a total failure, except in some fortunate instances where a liberal course of artificial watering could be given.

It should always be remembered, however, that during dry weather outdoor Roses should have thorough cultivation, and with a proper use of manure a fair sprinkling of flowers may be secured after the main crop is past.

Some Japanese Bamboos.

LAST year I noted in GARDEN AND FOREST the hardiness of some half-dozen varieties of Japanese Bamboos which, without protection, survived the winter of 1890-91. The same plants also passed the last winter without injury, and there seems little doubt as to their being reliably hardy in this latitude. Further experience with them has, however, made me rather doubtful as to their value here under ordinary cultural conditions.

The Japanese Bamboos which are attainable seem to be all native of southern Japan. The French nurserymen have sent these out under names of their own, generally botanical ones, but a number received with the native names, through the courtesy of Mr. Woolson, seem to be duplicates of those from France. The Japanese, curiously enough, use Chinese names for these and other plants, as was found in tracing up the translations of the names among some of our mild-mannered Occidental merchants. For instance, the Japanese name for Bamboo is "Take," but botanically the Chinese "Chiku" is used in conjunction with the varietal name; thus *Kimmeichiku* is the square-stemmed Bamboo (Castelloni of the French); *Koku-*

chiku is the Black Bamboo (*B. nigra* in French catalogues); Hamchiku is the Spotted Bamboo. Coming from this warm section, which, I believe, has a somewhat humid atmosphere, the Bamboos seem to require a warmer spring than ours to give them an early start. In my garden, at least, which has a cold, clayey soil, they do not seem quite happy, and begin to make growth rather late in the spring. A temperature of sixty degrees and upward seems to be required to make them move. It is very probable that my plants, which have been established about two years, are in too heavy soil and in too dry a position to do their best, and that with careful planting and attention they might make a more thrifty growth, but I doubt if, with their late-moving habit, they are likely to prove satisfactory to any but growers who fancy unusual plants. They are the slowest of plants, also, to become established, and are not things to be shifted from one position to another at the pleasure of the grower.

As pot-plants for conservatory decoration they grow somewhat better, the humid atmosphere seeming to suit them, and their peculiar decorative value is useful among tropical plants. Being grown there they also resent moving outside, and quickly show their resentment by withering foliage. As far as my experience goes, I am forced to conclude at present that the Bamboos are in the garden much inferior in value to the other noble Grasses, as *Eulalias*, *Arundos*, *Erianthus*, etc., which so rapidly each season form grand masses of graceful foliage, and require little care or attention. However, as it is the uncommon and difficult plants which sometimes prove the most interesting, it is to be hoped that further trials of the Bamboos may allow more favorable reports.

J. N. Gerard.

Juncus effusus spiralis.—The spiral-leaved Rush is a curious and interesting plant. A typical Rush-leaf is as stiff and straight as possible, but this variety has smooth green leaves which twist into perfect spirals resembling exactly a wire corkscrew. It is, perhaps, useless to speculate on the conditions which have caused this otherwise modest plant to take on such a form. It is a low-growing plant with no climbing tendency, and the spiral has no apparent use beyond exciting curiosity. Like other Rushes it is a bog-plant, or one for wet places. *Juncus Zebrius*, the Zebra Rush, is another bog-plant well worth growing, the tall stems being striped green and white, and the plant having the appearance of a lot of porcupine-quills. It grows very thriftily in a pan immersed in water.

Iris tripetala flowered last week, quite finishing the season of the family. This is a native variety from Florida, seemingly not quite hardy here. The leaves are dwarf and somewhat glaucous. The flowers purple with wide falls.

The Forest.

The Forest as modified by Human Agency.—II.

THE following is a continuation of the extracts published last week from an introduction to a course of forestry-lectures delivered before the University of Edinburgh in their session 1891-92 by Colonel Bailey:

"But although the absence of sufficient home-grown produce has not hitherto caused much inconvenience, there is no doubt that, as time goes on, we shall have to go farther and farther afield for our supplies of timber; and that, partly owing to increased local demand in the foreign countries whence we have been accustomed to draw them, and partly to the productive power of the forests having become impaired by overcutting and other injurious treatment, our importations from several of the most important of those countries are falling off, and it may be safely predicted that these supplies will, in course of time, considerably decrease, and that the price of imported timber will rise in a corresponding degree. We may, of course, eventually be able to bring to market the produce of even the most inaccessible forests of the Dark Continent to supply our ever-increasing needs; but it must be said that our future supplies are by no means secured, and that the time has arrived at which it has become our duty to take stock of the situation, and to consider what can advantageously be done to increase the timber production of our islands, so that we may be in a better position than we now are to meet, as far as possible, any interruption in the steady current of our importations which might occur owing to a partial failure of our foreign sources of supply, to the outbreak of war or otherwise.

"Dr. Schlich estimates that we might be able to grow at home £13,000,000 worth out of the £23,000,000 worth of forest-produce we import annually; and the forests created with this

main object would give employment to a very large number of laborers, and would at the same time serve to protect agricultural crops from the effects of injurious winds, and to afford shelter to cattle and useful species of birds.

"The desired increase in the amount of home-grown timber might be obtained by taking measures: (1) To obtain from our existing woodlands the maximum quantity of the best kind of produce that the soil is capable of yielding; and (2) To increase the wooded area by planting and sowing up such portions of our waste lands as cannot be more profitably utilized. It must be confessed that to accomplish either of these things is not an easy matter in many parts of the kingdom, because, while some existing woods are maintained principally on account of their picturesque beauty, a much larger number are kept up as game-preserves, and their proprietors have no wish that they should be treated with a view to obtain from them their maximum yield of wood. Again, vast areas of ground in Scotland are kept under Heather as grouse-moors and so-called 'deer-forests,' which have hardly a tree upon them, and these are greatly valued for the sport which, in their present condition, they afford, so that their owners do not desire to convert them into forests of trees. But in spite of these disadvantages the area of woodland now available for systematic treatment is very considerable, and it might certainly be largely increased with great advantage to the proprietors of the land, as well as to the country at large, not only on account of the increased production of forest-produce, but also by reason of the larger employment of labor that would follow a movement to extend the forests. The following sentences are taken from a recent article in the *Times* newspaper on 'Men and Deer in Scotland': 'Deer-forests by no means bring their owners the large rentals popularly supposed. The famous Blackmount Forest does not yield, it would appear from the Crown agent's figures, sixpence an acre. The group of forests in Inverness-shire, belonging to Mrs. Chisholm, is let at about threepence an acre. Even one penny an acre is not an unknown rate. In Sutherlandshire sporting rents seem to be, on the whole, higher than elsewhere. But one shilling an acre would appear to be quite unusual; and we have no reason to think, notwithstanding the popularity of deer-stalking and the growth of wealth, that rents will improve. Many Highland proprietors let their shootings as regularly as they let their farms, and these are not times in which they are likely to turn a deaf ear to people who say, with any show of good sense, 'I can tell you how to make more out of your estate than by afforesting it.'"

"It is not necessary for me to say that 'afforestation,' in the sense in which it is here used, is the exact opposite of the kind of afforestation that we are assembled here to study, and how such a misleading term as 'forest' came to be applied to a tract of land which is devoid, or almost devoid, of trees, and on which it is not intended to promote the growth of trees, I cannot explain.* If the figures given in the *Times* are anything like correct, the rate per acre derivable from a deer-forest cannot be called high. The average profit on the whole of the French forests, taken together, was, for the three years immediately preceding 1886, about seven shillings an acre. But, of course, the really important point is the rate of interest on their capital value which shootings and forests respectively yield. Dr. Schlich, basing his calculation on Weise's *Yield Tables for the Scots Pine*, concludes that land which cannot be let for the raising of field crops, for shooting, or other purposes, at a minimum rental of two and a half per cent. on the value of the land, may with advantage be planted up with Scotch Pine or other similarly remunerative tree; and I fancy that, even after excluding bare upper ranges, which it would not pay to deal with, a good deal of land in Scotland would be found to fall within this definition.

"Forests are not so exhausting to the soil as agricultural crops; for in the case of the latter the entire plant, except the roots, which are sometimes also taken, is removed; whereas in the case of a crop of trees, the leaves, flowers and fruit, which are far richer in nutritive elements than the wood, are annually returned to the soil, and thus serve to maintain its productive power, as well as, by their protective action, to keep it in a good physical condition. Hence forests can flourish on comparatively poor soil; some kinds of trees, notably most of the conifers, including the Scots Pine, being able to grow on ground that would be quite incapable of producing a series of remunerative agricultural crops. It is, therefore, generally speaking, not necessary to select rich fertile soils for the raising of forests, which ought rather to be established and maintained on ground which cannot be profitably

*I have since been told that the ground is supposed to carry a "forest" of antlers!

cultivated. Scotland has a large extent of land of this kind, which could be planted up without detriment to the sporting interests; and there seems no reason why this country should not be able to produce as fine and valuable timber as is obtained from the shores of the Baltic and from other parts of northern Europe. There is, then, plenty of work before Scottish foresters, both in the way of making the most of existing woodlands and of planting up new areas; and the object of the present course of lectures is to impart to the younger aspirants after fame in this direction some of the leading principles that should guide their endeavors.

"It seems, at first sight, marvelous that the United Kingdom should, until very recently, have been without the means of imparting any regular instruction in this important science; but the fact appears less remarkable when we consider how far cultivated land and pasture have with us taken the place of forest, the large extent to which we have drawn our supplies of timber from abroad, and the comparatively small amount of wood we consume as fuel. There is, however, no doubt another reason why progress in this direction has been so long delayed, and that is the very small area of forest-land in these islands which is owned by the state. In countries where extensive forests are state property, forest-schools were long ago established. I will instance the case of France, with the forests of which country I am better acquainted than I am with those of any other. The forests of France are thus owned:

	Square miles.	
By the state,	3,734=10.7 per cent.	
" communes or parishes, and public institutions under state control,	8,073=22.7 "	
" private proprietors,	23,657=66.6 "	
Total,	35,464	

"Although the state and the communes or parishes together possess only one-third of the total forest-area, the extent of their property is very large, amounting in all to 11,807 square miles. To carry on the management of these large domains, the state maintains a body of highly skilled foresters, who, before their appointment, have received two years' training at the National Forest School at Nancy, at which institution, until a few years ago, candidates for the Indian Forest Service also received their professional education. But it is a remarkable fact, that although private proprietors own no less than 23,657 square miles of forest, or double the amount owned by the state and the parishes together, there is not a single private forest school or class throughout the country; and further than this, although the lectures at the State Forest School are open to the public, advantage is very rarely taken of this privilege by private proprietors. This fact is doubtless due in a large measure to the succession laws of France, which tend to form very small properties; but there are still many large properties with valuable forests upon them, and the explanation of the abstention of private proprietors from any attempt to avail themselves of the means of instruction in forestry which are afforded to them and to their wood-managers is said to be that, as the state forests and the officials in charge of them are scattered about the country, the art of forest-management is more or less popularly known; that private owners have before them the state forests, which serve as models for the management of their own timber estates; and that they can get a certain amount of advice and assistance from state officials, who are occasionally permitted to render aid in this way. But in many localities the private woods are too distant from state or parish forests to permit of their owners obtaining any assistance from the government officials; and they are then thrown entirely on their own resources, with the result that although, speaking generally, the principal private forests are well managed, mistakes, and grave ones, are frequently made.

"I may perhaps here mention that in France private proprietors cannot clear any wooded area without notifying their intention to do so at least four months beforehand; and the government officials can, with certain exceptions, successfully oppose the clearance, if the continued maintenance of the wood is considered advisable on any of the following grounds, viz.:

1. To protect mountain slopes.
2. To protect the soil from erosion, and to hinder encroachments by rivers, streams or torrents.
3. To preserve springs and watercourses.
4. To protect coasts against erosion by the sea, and against the encroachments of moving sand.
5. For the defense of the national frontier.
6. For sanitary reasons.

"But although private proprietors in our country are not subjected to any such interference with the disposal of their property, they have none of the advantages which the existence of extensive state forests, and the presence among them of state forest-officials, gives to private proprietors in France; and in these islands the science of forestry is almost unknown outside a small circle of professional men, who, to their credit be it spoken, have acquired the valuable practical knowledge they possess without any of the advantages afforded by a previous study of the principles evolved by experience in countries where systematic forest-management has been long practised.

"But, in spite of these disadvantages, Scotland can show numerous well-managed forest-estates—such, for example, as those of the Duke of Athole, of the Earls of Mansfield and Seafield, of Lord Lovat, and of other proprietors who might be mentioned; and it is universally admitted that the art of raising nursery plants, of establishing plantations, and of rearing park trees is here carried out with a success unsurpassed by the foresters of any other country. Our Forest-class has thus the great advantage that excellent practical instruction in work of this kind can conveniently be given to it.

"It is impossible to mention the Duke of Athole's forests without alluding to the loss we have recently sustained by the death of Mr. John Macgregor, a representative Scottish forester, who has done much to forward the progress of forestry in this country, and whose well-known figure will be missed from among us for many a year to come.

"But I believe I am justified in saying that certain branches of the science have unavoidably received less attention than is desirable. I allude principally to regeneration by natural means (that is, felling in such a manner that the old trees may be caused to produce their successors in the form of self-sown seedlings), and to the preparation of working plans or schemes of management, by means of which continuity in the system of treatment is secured, the forest is made to yield the maximum quantity of the most paying kind of produce, and provision is made for the removal of a regular annual or other periodical yield; at the same time the owner is enabled to realize the full yield with confidence, and his forest is secured against damage by overfelling."

Correspondence.

Orchard Spraying.

To the Editor of GARDEN AND FOREST:

Sir,—I have read with interest the comments of Professor Bailey upon my observations on the question of insecticide and fungicide spraying. On some points I quite coincide with what he says. On others I remain in doubt, and the subject will bear more and fuller discussion before we lay it aside. Without doubt, the spraying will go on. I would be among the last to favor its prohibition. Its immediate benefits are manifestly important. Some crops would be prompt and utter failures without it. For years I have sprayed for the currant-worm, the cabbage-worm and the potato-bug, and have tried to destroy the onion-maggot by scalding, with considerable success. Squashes, melons and cucumbers I have "bugged" sedulously; but all the time I have been thinking how it was that the world got along in this matter before hellebore and Paris-green made their advent on the farm and in the garden.

When I began farming in northern Vermont, of all these pests only the squash "bug" (striped) was known here; but as the currant and cabbage worms were both imported to this continent by the way of Canadian seaports, I made their acquaintance some years before their moths had fluttered their way down to the vicinity of New York. The only great insect pest on the farm I had before known was the wheat-midge (misnamed "weevil" by the farmers), which, in two or three years, abolished the leading commercial crop of northern New England. For near thirty years wheat was a blank in the crop returns of this section; but we are now growing it with as good success as of old. Of fungous attacks, the only serious one in those days was the potato-rot. But the wheat-midge and the potato-rot were severe blows to New England agriculture, and became determining factors in the great western emigration which has kept the rural population of northern New England stationary for the last four decades.

The most noteworthy fact in all this is, perhaps, that both the insect and the fungous plagues abated, and practically ceased to be prohibitory to the cultivator, without other than natural aids. It is a most interesting question, whether, in availing ourselves of poisons, we are not at the same time prolonging the evils, or, perhaps, making them persistent. No one can

deter, and no one would wish to deter, cultivators from protecting their crops by the use of insecticides so long as it is profitable to do so. In suggesting that in orcharding, at least, we might find an easier and better way out by the adoption of species and varieties of greater resisting capacity than those we at present possess, I but point out a resource which has not yet attracted much attention except among the fruit-growers of the cold north, who have been forced for quite other reasons to become familiar with a distinct class of tree-fruits—namely, those of north-eastern Europe and north-eastern Asia. Primarily, these were brought to America because of their hardness against cold. Experience is showing us that they also excel our older fruits, derived from western Europe, in other important points; and among these are those very troubles for relief from which the orchardists of our states of milder climate are resorting so extensively to fungicide and insecticide spraying.

Among the greatest difficulties encountered in our earlier efforts toward orcharding in the north-east was the fact that even when we got hold of tolerably hardy varieties of the old stock—such as Fameuse and McIntosh Red—we found them falling speedy victims to fungous spotting. Growing alongside of these strongest among the weaklings, however, we could but notice the very different conditions of the few trees of the early importation, via England, of Russian apples. Quite free from fungi, and much less injured by the Codlin worm, these Russians attracted marked attention, in contrast with the few kinds of the old stock which we grew, but only at "a poor dying rate." Now, I am not a monomaniac on these eastern apples and pears, or on anything else, I hope; but this I know, that whereas once I despaired of our ever establishing orcharding on a commercial basis in northern New England, Quebec and New Brunswick, now, by the introduction of these fruit-trees of Russia, we are being rapidly placed in a better position than the great fruit-growing middle states. And while I am quite desirous that these iron-clads should be better known and understood in that section where they are most needed, I also want their good qualities to become known elsewhere. I believe the time will come when their wider adaptation to all of North America, east of the Rockies, will be understood, and the work of replacing with them the orchards of the less well-adapted fruits of western Europe be taken up. Certainly, the strongest protection of our orchards must be found in the vigorous organization of the trees which compose them. This is equally true as against climate, insects and fungi.

It was certainly an astonishment to me to read in Professor Bailey's article the statement, that if every variety of Apple subject to apple-scab were uprooted, "then, in western New York, at least, we should have no market apples left." I cannot suspect a man of scientific training of exaggeration, yet I can hardly conceive of this state of things as being true. If it be generally true, then the orchardists of our middle states cannot too soon give their attention to the selection of better varieties of apples from a more vigorous race. The apple-scab fungus attacks both leaf and fruit. Its seat is, primarily, upon the leaf, but the constitutional defect which admits of its attacks adheres in the entire tree, and in the race of trees so subject. The remedy, therefore, must be a radical one. Decadence is sure in the orchards of New York, unless such a radical remedy is found. The pomologists attached to the agricultural schools of the states where this disease of the apple prevails should not be satisfied with palliatives, but should earnestly study to understand and master the whole array of facts regarding the tree-fruits of other continents and their adaptation to our own.

This is a wider field than I ever expected to enter upon in my pomological studies. I can only indicate a path for younger men to explore.

Newport, Vt.

T. H. Hoskins.

Recent Publications.

The Massachusetts Society for Promoting Agriculture. Centennial year (1792-1892).

In this modest volume of 146 pages there is simply told something of the history and achievements of this venerable, although still active, society, which, a few weeks ago, celebrated the centennial anniversary of its organization on the 14th of June, 1792, although it had been incorporated by an act of the Massachusetts Legislature passed on March 7th of that year. John Hancock, as Governor of the Commonwealth, signed the deed of incorporation, and the name of Samuel Adams appears at the head of the list of the incorporators.

It is interesting to note that the Massachusetts society ante-

dates all others in that state, and, as a corporation, all similar societies in the United States, although associations for the advancement of agriculture had been established a few years earlier in New York and Pennsylvania; there was an earlier society in Canada, while in Great Britain, to which we are accustomed to look for agricultural leadership, little had been done until the beginning of the present century in organizing agricultural education, although at the time the citizens of Boston were engaged in this work the Dublin Agricultural Society, for many years a feeble body, was in existence, and the Highland Society had been incorporated in 1778. The British Board of Agriculture was not established, however, until 1793.

From the beginning the Massachusetts Society has been managed by a board of twelve trustees, including the president, two vice-presidents, a treasurer, and recording and corresponding secretaries, and it is an interesting fact, suggestive of the stability of Massachusetts families, that the same names appear generation after generation in the roll of the trustees; it is pleasant, too, to note that a member of the present board, a man honored for learning, integrity and public spirit, is the great-grandson of the first vice-president and of the first president, and the grandson of the sixth president. There is, perhaps, no other roll of officers of a corporate society in the United States which contains the names of such a list of distinguished men, and, certainly, no other organization of the kind has done more to promote the agricultural development of the country. Thomas Russell, the first president of the society, was one of the foremost and most prosperous citizens of Boston, the first president of the Massachusetts Bank, organized in 1784, of the United States Branch Bank at its organization in 1792, and of the Charles River Bridge Corporation. In the list of petitioners for the society appear, too, such well-known names as Martin Brimmer, John Codman, Christopher Gore, a senator in Congress from 1813 to 1816 and a benefactor of Harvard College by a gift of \$100,000, at that time an enormous sum; of Benjamin Guild, Steven Higginson, John Lowell, Jonathan Mason, David Sears and Thomas L. Winthrop. John Adams was president of the society from 1805 to 1813. Among the trustees have been three generations of John Lowells. John Thornton Kirkland, afterward president of Harvard College, was a trustee from 1798 to 1811. Fisher Ames served on the board from 1800 to 1804, and Josiah Quincy from 1805 to 1809. Daniel Webster, who took a deep interest in its proceedings, was a trustee from 1833 to 1853, Edward Everett from 1850 to 1855, and Robert C. Winthrop from 1853 to 1862; and there is hardly a family that has been prominent in the last hundred years in building up the material prosperity of the commonwealth which has not had its representative at some time or other on this board.

This is hardly the occasion to recite all that the society has accomplished for agriculture, as the term is usually understood, in the past hundred years; but the trustees have administered their trust in a broad and intelligent spirit, and we find that, in addition to the improvement of live stock and the increase of good tillage, they have been occupied from very early days in developing the knowledge of botany, horticulture and silviculture.

At the second meeting of the society a paper on the diseases of fruit-trees, that had been recently printed by William Forsyth, gardener to the King of England, was read and afterward reprinted in the society proceedings. At the meeting held in January, 1793, the society voted to offer two premiums, the first in its history, for "the most satisfactory account of the natural history of the Canker-worm" and "for the most effectual and cheapest method of destroying these insects." The trustees, in February, 1794, appointed a committee "to consider the expediency of procuring a piece of ground for the purpose of agricultural experiments." Finally, this project took a different shape, and led to the establishment of the Botanic Garden at Cambridge. In 1801, the society voted to appropriate \$500 toward the foundation at Harvard College of a professorship of natural history, which was finally established in 1804. The plan, so far as connected with the object of the society, provided for the scientific observation of the growth of plants and of the habits of insects injurious to them, and for the cultivation for sale and distribution of the seeds and roots of useful plants. The co-operation of the society and the college in conducting the Botanic Garden continued for a quarter of a century, during which period the society voted annually a sum of money from its own funds for carrying on the garden. The Harvard garden was the first botanic garden connected with a public institution founded in the New World, the only earlier garden of scientific reputation having been the so-called botanic garden

of John Bartram, the Philadelphia botanist, which was a private and not a public garden.

The prize offered by the society for the essay on Canker-worms was awarded to Mr. W. D. Peck, who was the first occupant of the chair of natural history in Harvard College, and it was by him that this garden was laid out, which has since obtained a world-wide reputation from the fact that for nearly half a century it was the home of Asa Gray. In late years the society has aided, by sums of money, the Botanic Garden, the Arnold Arboretum and the Bussey Institution of Harvard College. It has made possible the publication of important scientific papers like Professor Farlow's essay on the Black Knot; it has published a translation of De Cars's treatise on the pruning of forest-trees, and has stimulated tree-planting by the offer of large and comprehensive premiums.

F. A. Michaux, the author of the classical work on North American trees, was an honorary member of the society, and at his death showed his appreciation of its worth by bequeathing to it a considerable sum of money as a testimonial of gratitude to the hospitality and assistance which he and his father had received in this country during the course of long and toilsome journeys.

The proceedings of the society which, unfortunately, were discontinued many years ago, contain the best record of the early agricultural and horticultural development of New England and are a monument to the industry, zeal and intelligence of the early trustees. In them will be found the record of many interesting investigations and of much good work.

We have only mentioned briefly the efforts of the officers of the Massachusetts Society to improve those departments of rural economy in which the readers of this journal are most directly interested, but farmers will find in this record of its work much to interest and stimulate them. Its centennial volume is printed, we understand, for gratuitous distribution, and can doubtless be obtained from the recording secretary, Mr. Francis H. Appleton, of Boston.

Notes.

It is stated that the damage from blight, mildew, rot and yellows done to the fruit crop of the country amounts to not less than \$50,000,000 annually.

A place of interest to all lovers of the history of the art of gardening, Alexander Pope's villa at Twickenham, on the Thames, is now for sale. For nearly twenty-five years it has been occupied by Mr. Henry Labouchère.

The August number of *Mechans' Monthly* speaks of the Edmonds Pear, as it has fruited in Germantown, as rather larger than the Duchesse d'Angouleme, although the quality is not quite as good, or perhaps it should be stated that the flesh is lacking in the juiciness which characterizes the Duchesse. It is one of those pears which ripen first from the inside while the outer part is still solid, although in good condition to be eaten.

An attempt has just been made to send fresh fruits direct from California to England, a consignment having recently been shipped from this port by the swift steamer *Majestic*. A train of five cars left Sacramento at ten o'clock one Monday night, and reached New York on the Tuesday of the following week, and its burden was immediately transferred to the vessel, which had been fitted with refrigerators capacious enough to receive the entire quantity.

Mr. Thomas Griffin, of Westbury, Long Island, brought to this office last week some remarkably good flowers of the Tuberos Begonia, of which he makes a specialty. We were particularly interested in the strain which seems to have a distinct Tea Rose fragrance. The specimens we saw were all single-flowered, and in color they were pure white at the base of the petals, shading to a clear pink on the border. Mr. Griffin stated, however, that he had fragrant flowers in all colors, ranging between pure white and a dull red. He also states that he has some semi-double flowers which have a distinct fragrance.

The Hard Hack (*Spiræa tomentosa*), which is now blooming by many country road-sides, is a shrub that deserves more attention than it has received. The short racemes of rose-colored flowers are crowded into a dense panicle, and they remain open a long time in the season when few shrubs are in bloom. Among the herbaceous native species the Queen of the Prairies (*S. labata*) is also worth cultivating, as well as the Goat's-beard (*S. Aruncus*), although they are now both past their bloom. This last one, often seen in European gardens, is a plant of noble bearing, and its panicles of creamy flowers

attain magnificent proportions in deep rich soil. There is great difference in the quality of the flowers of *S. palmata*. In one variety they are of a bright rose-color and have a distinct fragrance.

The "Listener," of the Boston *Transcript*, recently described a Currant-bush filled with ripe fruit which he had seen growing in the fork made by the principal branches of the so-called Washington Elm at the village of Wellesley, near Newton Lower Falls, not far from Boston. The trunk of this tree—under which Washington is said to have halted when on his way to take command of the army at Cambridge—is much larger than that of the Washington Elm in the latter place, beneath which the ceremony was performed. Life, however, is left in only one of the great branches into which it divides. The Currant-bush, conspicuous at all times, but especially when loaded with scarlet fruit, flourishes about twenty-five feet above the ground.

"The engaging heroine of a play," says Mr. W. D. Adams, in his "With Poets and Players," "is never or rarely without her flower-basket or artlessly arranged bouquet. . . . All eligible young ladies in stageland have a passion for 'the stars that in earth's firmament do shine.' They stick them in their hair or in their waist-bands, but most frequently they carry them prettily in their hands. They usually make their entrée in that manner. They convey the impression that floriculture is the badge of all the feminine tribe—or of all, at any rate, that is young, and handsome and ingenious. When they sit down it is to play artlessly with the flowers in their laps. Apparently the stage demoiselle has nothing whatever to do but to sort and arrange these things. The more interesting the conversation, the more patiently she goes on sorting and arranging them. When the talk flags, she walks over to a table and distributes them among the vases, taking great pains about their appropriate disposal. On the boards the difficulty is to know what to do with one's hands, and leading ladies solve the problem by coming laden with flowers."

We cannot too often call our readers' attention to the good work being done by the Flower and Fruit Mission in this city, and to the little trouble it costs persons in the country to contribute from their overflowing stores of flowers. The headquarters of the mission are at 104 East Twentieth Street. It is open, for the distribution of flowers, fruits, fans and other articles comforting to the poor and sick, on Mondays and Thursdays; and packages addressed to it are carried free by the express companies. Although as many as eight thousand little bouquets have sometimes been sent out in a single day, more are needed; and gifts are especially welcome when donors spare the busy distributors extra work by themselves tying up the flowers in small and tasteful bunches. They go to the prisons, the almshouses, the hospitals and the tenement-houses; and in all of these places even a single blossom is hailed with delight by persons who seem sunk beneath any good or pleasant influence. The mission tells of one sick old woman who will not part from her withered bouquet until a kind hand brings her a fresh one to replace it; and if all the pathetic stories which might be told could only be rehearsed in public hearing, the packages received at the mission would surely increase at a rapid rate.

It takes a big pile of kindling-wood, says the *Northwestern Lumberman*, of Chicago, to start the fires in the stoves of a large city every day. Suppose a small armful is used in a stove, and that there are a quarter of a million or more stoves, as there are in this city, and it can be seen that it would keep a good many slabbing saws busy to supply the demand. The kindling-wood business of Chicago has passed through one period, and has now reached another. Heretofore it has been no trouble to get kindling. Slabs were bought sawed or unsawed, as the case might be, and the servant-girl was at liberty to use all of them she wanted to. But now they are becoming a luxury. Ask any wood-yard man doing a business of any size, how his stock of dry slabs is, and he would say that he stands ready to buy a hundred car-loads. Old plank sidewalks, which are being replaced with concrete, are cut up into kindling. Such walks are speculated in to about the extent that wheat is over on the Board of Trade. Not long ago a North-sider sold an old walk to a woodman for \$6.00, and without handling a plank of it the walk was sold for \$107. And that price, too, was paid for it for kindling-wood. So you see the wasteful period of the kindling-wood business has been passed through. Not in the far future, we suppose, the Chicagoan, like the New Yorker, when he builds his fire, will toss in the stove a little bundle of slivers all tarred and tied up for the occasion.

Taste Indoors and Out.

THAT cultivated Americans have a natural sense of fitness in dress and household adornment is admitted by even the critical French nation, which is more secure than any in matters of taste; but when they undertake to deal with the problem of the arrangement of grounds it is curious to see how their sense of proportion and appropriateness fails them, and how people who would not permit a discordant rug in their drawing-rooms or an ugly book-case in a library or an undesirable horse in their stables, will allow incongruous trees and shrubs to be planted, and unsightly rockeries and flower-beds to be cultivated in the wrong places about their houses. The perception of breadth and unity seems hard for them to attain, possibly because people are by nature more imitative than original, and our civilization as yet affords them but few good examples to copy.

In an untraveled department of art people are apt to go astray, to consider that what they like is necessarily a good thing. Original conservation makes men hesitate to make new departures. They fear to cut away a tree because it is itself beautiful, and fail to grasp the broad effects of landscape that may result from judicious destruction. A vein of sentimentalism, of association, of fancied picturesqueness, mars their final effects. Women, especially, may be great in a flower-garden—they are seldom great on an estate where prettiness, variety, daintiness, delicacy are required—there they shine; but landscape-gardening on a large scale is, after all, a masculine art, and requires a certain manly vigor of treatment, an unhesitating despotism, that the gentler sex deprecate as cruel and unnecessary. Women may be generally held responsible for the false details we so much deplore, because American men, as a general thing, are too much occupied to give much attention to their grounds

and leave their arrangement to their gardener and their womankind.

The former is naturally a good right arm, sometimes opinionated and lacking in that broad experience only to be obtained by travel and study. In his own sphere he shines, but it is not his business to be an artist. When he attains that distinction he abandons gardening and looks for work of wider range and greater opportunities.

But there is no reason why a woman of taste should not master the science of outdoor beauty, and conform her arrangements to its rules rather than to her own caprice. It is not an exact science, to be sure, but still landscape-gardening has its laws as well as household arrangement, laws which, while permitting great variety, still give a test by which to distinguish between the true and the false, the meretricious and the really beautiful. The knowledge of how to create and to preserve the beauty of one's surroundings is surely as valuable as a sure taste in carpets and draperies, but it is rarer to find. That it prevails more widely in the older world is partly due to the more stable conditions of residence, the maintenance of an estate by one family for many generations, an early familiarity with cultivated grounds, and free access to public places and parks which have been laid out by men of real knowledge and highly trained perceptions.

Here we come to the subject in our maturity, a man buys a place after he has made his fortune, accepts the conditions of his predecessor without question, or goes to work to alter them without much consideration. The mistress of the estate, with still less training and experience, undertakes to decide where things shall be planted, and what they shall be, often with melancholy results. Sometimes the theory of letting things alone is carried to excess. Wild shrubs and weeds are allowed to encroach too closely upon a stately house; dignity is sacrificed to a picturesqueness which is out of place. The fact is ignored that things which in themselves have beauty are not necessarily appropriate for formal uses. To understand the proper subordination of nature to art requires the most subtle perception and trained skill. Again, the relation of fences to an establishment is not always given due consideration. There is a taste in gate-posts as well as veranda-columns, which often goes astray. Refinement in every detail is as essential in well-kept grounds as in a drawing-room; a false note struck is a distress; a picturesque object in the midst of a formal arrangement is a mistake. Overcrowding is a prevailing fault; there is excess of decoration where quietness should prevail; feeble and unimportant shrubs and trees are allowed to overpower more valuable neighbors to the detriment of the place; gay flowers are planted where they are out of key with the surroundings; clutter takes the place of repose; a thicket supplants a pleasing group of trees or shrubbery.

All this shows that taste can be highly cultivated in one direction, and starved in another, and the question is, which stands for the highest type of civilization, a knowledge of the fitness of things in the interior of the house, or the same knowledge applied to its surroundings? Taste in outside matters is certainly rarer than in household decoration or in architecture; a demand for the landscape-architect is in this country almost an evolution of to-day. That he is sorely needed the condition of many country places shows, and there is a call for men of genius in the profession to establish a standard, not necessarily a conventional or a rigid one, but something which shall afford a criterion of taste in the arrangement of pleasure-grounds and make of the adornment of country places a less haphazard thing than it is to-day, when it depends almost entirely upon individual fancy.

Life in the country gains more and more a hold upon our branch of the English people, and we begin to develop the same interest in it that has characterized the older branch, as our habits become more settled and permanent. The time is probably coming when the nomadic habits of Americans will change for a more conservative way of

living, and the possession of land as it grows rarer will be more dearly prized. Therefore, taste in the management of estates will grow and improve along the lines that are indicated for it, and it is important that such taste should be guided in the right directions, and taught to seek for the best models, rather than be allowed to grope wildly in search of beauty, which, after all, though sometimes attained by a happy chance, is really within the reach of all landholders by careful planting and thinning of vegetation. And we would urge upon women to address themselves to the acquirement of solid knowledge on this subject, as the best foundation for taste in the arrangement of their grounds. It is a healthful, beautiful and useful pursuit, far more valuable than the decoration of bits of china or the production of amateur pictures of doubtful value, on which they waste so much time that might be better employed.

The same amount of thought and time and artistic perception that goes to the production of a trifling sketch might well be turned to account in the manipulation of growing things, in the planning of a rustic dell, the preparation of some pleasing surprise at the end of a shady walk through extensive grounds, the discovery of a hidden point of view, and skillful use of it, the construction of some dainty bit of garden in an unexpected spot. All this would be of value to feminine development, both physical and mental, and by such exercise her taste would grow more secure, her thoughts would be filled with natural objects in their relation to each other, and a country life be made fruitful in health, and in a growth of perception of true beauty.

By Bicycle to the Waverley Oaks.—I.

WHERE the roads are as good as those about Boston the bicycle has provided those who keep no horses or carriages an easy and delightful means of visiting the beautiful spots in their neighborhood. The wheelman needs to study no time-table, but is always ready to visit any pleasant spot within a range of ten or fifteen miles, and in the course of a season I have become familiar with all the aspects worn by many such spots. Close at hand, for instance, are the Middlesex Fells and the Pine Banks, coursed by several miles of beautiful roads. Both are probably destined to become important features of Boston's metropolitan park system. The Lynn Woods are only a few miles away, and a most attractive woodland and rural country intervenes, some of which, in the valley of the Saugus River, is, perhaps, destined to reservation for park purposes. The Lynn Woods, by the way, have just been still further enlarged by the addition of the hilly and well-wooded Ox Pasture region lying to the northward of Glen Lewis and Walden Ponds. This tract includes the celebrated old wolf-pits built by the early settlers. It adds about four hundred acres to the public domain, which it increases to an area of something like a round two thousand acres. As this tract is on the water-shed of the aforementioned ponds, which form an important source of the Lynn water-supply, it was taken by the Water Board to assure freedom from possible pollution by future occupancy. A few thousand dollars now spent in the way of precaution undoubtedly saves a future expenditure of many thousands by way of remedy. This commendable step of the Lynn Water Board is largely due to the wise counsel of Mr. Philip A. Chase, the chairman of Lynn Park Commission, who has done so much toward the realization of this noble public forest.

It was a cloudless July day when I mounted my light roadster for a run to the Waverley Oaks. In spite of the exercise, the wheelman who takes an easy pace on a hot day is little troubled by the temperature. Indeed, he feels the heat less than if he were keeping still. If the air is calm, the motion fans him with a gentle breeze, and on returning home he is often surprised to learn what a hot day it has been. The way from Malden to Belmont is full of interest; and owing to abundant rains, forest and field are delightfully fresh and green this year. The first part of the way is over the historic old Salem road, the first highway connecting the original settlements of the Massachusetts Bay Colony, Boston and Charlestown, with Lynn and Salem. A wild and solemn old road it must have been at first, cautiously traversed by the early settlers, haunted by fears of Indians and wild beasts. A large portion of the way it still bears the name of Salem Street. At Med-

ford it now becomes Main Street; there it turns sharply to the left from the old town square and crosses the Mystic River by the single stone arch of the Cradock Bridge. This crossing of the Mystic is the reason for the roundabout course of the old Salem highway, which, on this account, makes a detour of several miles from a straight course. For at this point, in the old days, was the first practicable ford of the Mystic passable, of course, only at low water—hence the name of Medford, which, unlike most of the old towns, has no English name-sake, but is derived from "Meadow Ford." The Mystic River gets its name from the Indian "Mistuck," which means a great tidal stream.

The rocky heights of the Middlesex Fells trend off to the north-westward, and Salem Street turns from their base across the Medford plains. These plains were once covered with noble great Oaks, whose existence near the river gave birth to the now vanished ship-building industry, which made the A No. 1 Mystic-built craft of Medford famous for their sterling qualities all over the world. Here at Medford was built the first vessel in the Colony, the Blessing of the Bay. These Oaks of the Medford plains rivaled those of Waverley, as may be seen by a fortunately surviving group on the beautiful old Governor Brooks' place, at West Medford. All but a few trees of the woodland that, until lately, still remained on the plains have vanished before the Gypsy Moth crusade, and new suburban streets are covering the territory.

Through Medford we pass by a number of interesting old colonial houses, up the hill over High Street, overlooking the Mystic. The stately old Unitarian church, where John Pierpont used to preach, stands at the top of the hill, and just beyond, on the other side, is the picturesque Episcopal church, one of Richardson's early designs in Gothic, built of field boulders and mantled with both English and Japanese Ivy. If the Metropolitan Park Commission lays out a Mystic Valley Park, as has been suggested, this hill-slope of old Medford, with its old-fashioned tree-embowered houses, and its two characteristic church spires—old Colonial, in wood, and English village, Gothic, in stone—will make a notable feature in the landscape.

The road to Arlington passes by the lower part of the Governor Brooks' place and crosses the Mystic by a wooden bridge near the mouth of the lower Mystic Pond, up which there is a lovely vista of blue waters, backed by the high slopes of the Woburn, Lexington and Arlington hills. Arlington and Belmont are in the land of market-gardens, which place some of the Boston suburban towns in the foremost rank of Massachusetts agricultural communities. On the left we pass a row of greenhouses bordered by a line of electric arc-lights, the scene of what I am told is a very successful experiment in the commercial application of electricity to hastening the growth of plants and market vegetables. The air at intervals along our route through these two towns is redolent with the pungent odor of growing cabbage, cauliflower and onions.

Arlington is the historic Menotomy of the revolutionary days. The old Cooper's Tavern, where two of the Minute Men were killed by the British on their retreat from Lexington, still stands on the corner as we turn into the wide main highway that comes from Cambridge. It bears the old name on its brick sides, with suitable inscriptions concerning its history, but in front there is the commonplace designation of "Arlington House." It would be well to drop the new name. A house with such a history should not cheapen itself with an alias.

We pass but a few rods along the famous highway down which the sadly harassed British troops came back from Lexington on that memorable 19th of April, a day as hot and beautiful as this July day. Beyond the railway station we turn into the Elm-arched road to Belmont, which resembles a long Gothic cathedral nave, and its solid macadam surface has been rolled to perfect smoothness. This street is well worth the tribute paid it by Trowbridge, one of the most genuine of American poets, in his poem called "Pleasant Street." On the left, occasional glimpses of Spy Pond, one of the beautiful lakes of the Boston suburbs, are caught through intervening trees and dwellings. As with most of the other suburban lakes, no attempt has been made to give the public the advantage of a landscape feature such as many a city in the Old World would give hundreds of thousands of dollars to possess. Spy Pond forms a charming and valuable feature of the estates whose fine grounds border it. But, as the population in the metropolitan district becomes denser, and land increases in value, the shores of all these ponds are likely to become disfigured with unsightly dwellings and skirted by various nuisances, until they are transformed from public adornments into eyesores.

In Lynn, Melrose and elsewhere this process of deterioration is well under way. In the former municipality, thanks to the thoughtful initiative of Mr. Chase, the first steps toward a better condition of things have been taken in the purchase of a narrow strip between the street and Flax Pond, near the entrance to Lynn Woods, covered with a fine grove of White Pines.

How much more valuable to the town of Arlington would be Spy Pond were its shores skirted by pleasant paths and drive-ways, with the intervening land reserved to the public and tastefully planted! What an exquisite effect would masses of Rhododendrons, Azaleas and other blossoming shrubs make upon the borders of these ponds, clustered among the trees and other natural growth of the localities.

The proper treatment of all these suburban sheets of water should form an essential feature in the work of the Metropolitan Park Commission. The Boston Park Commission has recently taken the shores of Jamaica Pond, in West Roxbury, and that fine sheet of water will soon form a prominent feature of the Boston park system. The town of Wakefield has had the forethought to convert a large portion of the shores of Lake Quannapowitt into an attractive pleasure-ground; Cambridge has built a drive-way around Fresh Pond, hardly developing its landscape possibilities to the best advantage, however; and the several communities that derive their water-supply from Spot Pond, in the Middlesex Fells, have recently taken the entire shores of that exceptionally charming lake. This is about all that has been done in that direction in the Boston suburbs, as yet.

At the Belmont town-hall, a beautiful brick structure designed by Hartwell & Richardson, Pleasant Street turns to the right and runs along the slope of a narrow pass between the hills, in the depth of which there is just room enough for the Fitchburg and the Central Massachusetts Railroad tracks. Shortly beyond are the Waverley stations of the two lines, the most convenient point of approach for those visiting the Waverley Oaks. A few rods beyond the street leading from the railway stations our way dips into a sylvan glen where a large, clear and rapid brook crosses beneath a low rustic stone bridge, and a road to Lexington and Concord, called Mill Street, forks off to the right and passes up the hill. Near the bridge a guide-board bears the picturesque name of Partelo Road.

Boston.

Sylvester Baxter.

The Sugar Maple.

MAPLE-TREES are characteristic of northern Ohio, and add a distinctive and special beauty to the landscape. They are more abundant than other trees, and help to give that air of prosperity and luxuriance to the country that is missed as one journeys up the chain of the Great Lakes. To those who have lived among Sugar Maples and enjoyed their sweets in the early spring, and later the light of their willowy colored blossoms mingled with the tender red foliage of their kin, they become an essential feature in the spring opening. We love these annual displays as others love their native hills and mountains.

The blossom of the Red Maple is the true harbinger of spring. It is all fiction about the bluebird. He comes along in the late winter, and we find him half-frozen in the sleet, fluttering against our windows for light and warmth. But when these red tints begin to show themselves in the borders of the woods then we know that other trees are in a fair way to bloom, and that spring is surely coming. The Maple is not, as regards size, of exceptional growth. The dense foliage and cleanliness recommend it to the lover of shade, and its symmetrical shape renders it especially adapted to the road-side. One farmer in this locality, with an eye for artistic effect, years ago planted a row of Pines on one side of the road which passed through his farm, and on the other side a row of Maples; they were, doubtless, wisely cared for, for they stand now, in unbroken lines, vieing with each other in wondrous contrast, and make an avenue of an otherwise commonplace country road. The two varieties, commonly known as hard and soft Maple, make up the greater part of the trees which adorn our "Forest City." The fruit of both the Sugar and Red Maple is winged and similar in shape, but that of the Sugar Maple does not ripen until fall, sprouting the following spring, while that of the Red Maple ripens in early summer and germinates at once, making sturdy plants by fall. In this way the Red Maple obtains a year's start of the other species.

The Hard Maple is the most commonly tapped for sugar-making. Other species yield sweet sap, but their buds start earlier, and the finished product is thus rendered dark-colored and of

poor quality. Those who have made the industry of the manufacture of maple-sugar a study, estimate a net profit of ten per cent, on the capital invested. If this is the case there is no good reason why it should not be profitable, for, unless it be the Walnut, or possibly the Chestnut, there is no tree worth growing for its timber that will yield yearly so large an income. No great attention has been given to the making of maple-sugar as an industry, and until within a few years the methods of evaporation have been primitive and much of the product comparatively poor in quality, besides the waste from want of convenient receptacles for storing sap. Now, that it is so difficult to obtain unadulterated sweets and confectionery is such a doubtful compound, maple-sugar should be more highly prized, and more widely distributed in states where the Maple is not native. From the natural condition of things such a business will never become a monopoly, and there will always be a demand for the pure article.

The illustration of the Sugar Maple on page 380 is not that of a typical tree. It is of unusual size. The trunk, two feet from the ground, measures thirteen and a half feet in circumference, and the largest limb, at a convenient distance from the body, eight feet. The branches spread either way a distance of fifty feet, shading the ground a space of one hundred feet in diameter. The tree is tapped annually, apparently without impeding its growth or injuring it in any way, and it yields each year sufficient sap to make three gallons of syrup. It is a forest-seedling, and no one knows its age.

This magnificent Maple stands in the front dooryard of Mr. Luther Parker, a venerable gentleman eighty-three years of age, who values it above anything else upon his farm. It is on the well-known North Ridge Road, forty-five miles east of Cleveland.

Geneva, Ohio.

Floy L. Wright.

Notes on the Flora of Smyth County, Virginia.—II.

MANY of the tributaries of the Middle Fork of the Holston River, all noisy little brooks, rise on the Iron Mountain or on one of its spurs, Brushy Mountain. One of these streams, Staley's Creek, winds in and out among the little hills to the south-east of Marion, and it was along its swampy borders that we first saw specimens of *Magnolia Fraseri*. They were only slender little trees at that altitude, but were in full bloom. Some of the flowers were over five inches long, and each was surrounded with a rosette of the large, bright green, auricled leaves. It was interesting to note how the flowers faded to a dull leathery brown, and were reflexed back against the stem, where they remained some time before finally falling off. The Cucumber-tree (*M. acuminata*) was there also, with its much less showy, as well as smaller, flowers. It is a particularly handsome, stately tree, often seen growing to a great size along the high-roads. Staley's Creek was disfigured with a small saw-mill that has evidently perpetrated damage out of all proportion to its size. It has very successfully done away with all the larger Walnuts, Hickories and Ashes, and now White Oaks are being turned into hubs and spokes for wagon-wheels, handles for axes and hoes. Many a superb Chestnut Oak lies prostrate, bereft of its bark, great car-loads of which at Marion Station told only too plainly of the devastation in progress in the higher recesses of the mountains. On some of the hill-sides a few antiquated Chestnuts, and the tall straight trunks of the Sour Gum-tree (*Nyssa sylvatica*) are the only remnants of the older forests. The larger Nyssas were especially noticeable on account of the curious way their bark had of splitting into hexagonal sections.

The Sweet Buckeyes (*Æsculus flava*) grew along the streams, and were a fine sight, the dark bluish green of the foliage making a striking background for the splendid spikes of flowers. White-flowered shrubs were, however, at that season the most abundant. The Flowering Dogwood was in its glory, for as far as the eye could reach its snowy masses covered the hills. Some of the trees were remarkable for a very decided pink tinge to the flowers. It was more noticeable at a distance than close by, though in drying the flowers preserved the pink-streaked look of the bracts. Two White Thorns, *Cratægus coccinea* and *C. Crus-galli*, were abundant everywhere in the valley, and on the hills and along the road a few late-blooming Black Haws (*Viburnum prunifolium*) added their mite to the white festival.

The woods and swamps were filled with Violets, yellow, blue and white, too many to note separately. Among them all a pure white form of *Viola cucullata* was remarkable for its size and beauty. *Houstonia serpyllifolia*, the daintiest of tiny blue flowers, lined the borders of the little brooks with a starry growth. It was astonishing to see the size and beauty the little

flowers attained along some of the higher mountain-rills. In striking contrast in color was Phlox reptans, a pretty species of a clear rose-purple, with long trailing runners. The May-apple, or Mandrake, as it is called in many places (*Podophyllum peltatum*), was seen in every field on the edge of and in every wood all through the country. In the open it grew in dense patches, sometimes of nearly an acre in extent, and made its presence felt by its all-pervading perfume. The beautiful pink-purple and white *Orchis spectabilis* was abundant in damp woods, growing usually two or three together in a clump.

Polygonatum giganteum well deserved its name, for in many shady places the great light-green-leaved plants towered so high above us that we could look into its pretty bells. It was often found over six feet high. With it were always the Bellwort, *Uvularia perfoliata* and *Oakesia sessilifolia*. At a higher altitude above the creek on Pond Mountain, as elsewhere, between three and four thousand feet above sea-level, *O. puberula* was abundant, a brighter green-leaved and much more slender species than its two relatives just mentioned. With it on stony, dry and hot slopes the lovely Lily-of-the-valley (*Convallaria majalis*) was at home. Its habit in its native haunts is certainly very different from that which it has acquired in gardens. It stands up straight and stiff from among loose stones singly, never in dense clumps. At the same altitude, though it was also abundant in the valley, *Disporum lauginosum*, grew at its best. On one widely spreading luxuriant plant we counted fifteen of the yellowish green drooping flowers:

Along the dry summit of Pond Mountain the Virginia Snake-root (*Aristolochia Serpentaria*), with its strange, almost subterranean flowers and aromatic root, was a novelty to most of us. *Leucothoë recurva* was very abundant and very luxuriant along the top of the ridge. It is a beautiful little bush, two to four feet high, with rather straggling slender branches, and long, one-sided recurved racemes of snowy-white bells—one of the most striking of the mountain shrubs.

Early in June the valley beyond Pond Mountain was filled with Laurel (*Kalmia latifolia*), then just at its best. A large swampy tract of land filled with it, the spreading white cymes of *Viburnum cassnioides* and some delicate yellow *Rhododendron calendulaceum* made groups that any gardener would covet. The *Rhododendron* was very often met with, though with one exception never in great masses.

Five miles east of Marion, along a hollow filled with *R. maximum*, we found the rare *Carex Fraseri*. It is a singularly beautiful plant. The glossy, leathery leaves are from one to two feet long and over an inch wide, growing together in clumps and overhanging the banks of the creek, and the white spikes of flowers have somewhat the aspect of a small Blazing Star (*Chamælririum Carolinianum*). The latter, with splendid long fluffy white spikes, we found not far from where the *Carex* grew, but in more open sunny ground.

Rhododendron Catawbiense was at that time in full bloom. It grew in small clumps, isolated mostly along rocky ridges and in the lower valleys, never in great quantities. The large clusters of rose-lilac bells were very handsome. In some places the flowers were so light as to be almost white.

Along the wildest and most impassable portion of the thicket it was interesting to note some very fine tall Locust trees, which looked almost out of place in a truly wild state.

A few late specimens of the queer little *Obolaria Virginica* were still blooming, and near them a small group of the rare Putty-root (*Aplectrum hiemale*), a curious, though hardly beautiful plant. Two Lady's-slippers, the little yellow and brown *Cypripedium parviflorum* and the larger pinkish *C. acaule*, were invariably found growing together, and with the pretty little Swayblade (*Liparis liliifolia*) completed the list of Orchids growing along Nick's Creek.

Conspicuous all over the dry hillsides, where it always made a gay spot in the wood, was the brilliant Fire Pink (*Silene Virginica*). *Asclepias quadrifolia*, one of the most graceful of the Milkweed tribe, was often seen with it, and was equally pretty.

Anna Murray Vail.

Italian Garden Tools.

IN the course of a long residence in Italy, various things have struck me as novel and interesting in the horticulture of this ancient civilization, and it has seemed to me that your readers might be entertained by the same points which have attracted my attention; and to begin with, some of the implements used are so novel to American eyes, and have a character of their own so decided, that, perhaps, I may as well start with them.

The farmer in central Italy has half a dozen distinct tools which we Americans can only describe as spades; and one or two of these Tuscan varieties of the species might well find a place in our tool-houses. The Italian is an old hand with a spade. Since the days when Romulus made use of one to kill Remus, these rustic weapons have been the stand-by of the Roman farmer and his Italian successor. Plows, even the improved English article, are considered rather coarse and ineffectual substitutes for the spade. And, indeed, no plow could cut those broad, shoulder-deep trenches which are dug hereabout between the Vine-rows at least every other year. This trenching, by no means the lightest of the husbandman's labors, serves to prune the too luxuriant Vine-roots; but its chief end, in the farmer's eye, is the ventilation of the sub-soil; a process which he holds—as countless generations have held before him—to be absolutely necessary. Superstition, doubtless, has its part in this theory; still there is no question that in Italy freshly turned earth is unwholesome, and its neighborhood to be shunned, above all in the cities.

Now, for this trenching a spade like our own is sometimes used, or another with a slightly curving blade; but the favorite implement, and that which does the neatest work, has a flat blade about as long as our own and of the same width at the handle, but tapering thence to a sharp point. It can be seen at a glance, or rather at a blow, that this tool is much more easily handled than the one-edged spade, and Italians claim that this more than counterbalances its inferiority in carrying power. It is, at all events, especially adapted to the use of the contadina on her lonely farm, who else must wait impatiently till a man will spare the time to dig over her garden-plot; while on land caked by a July drought its pulverizing power cannot be overestimated. For summer weeding, it is in great favor with the Italians, who prefer to work the ground more deeply than is possible with a hoe; though here again one is often tempted to question whether so much extra labor is really necessary and profitable, or whether the reason why the imported hoes hang rusting in the hardware shops be not rather because the Roman of old made use of none such; albeit, of mattocks—the tool from which the hoe is evolved—he possessed an infinite variety. The persistence of these immemorial traditions, these elementary rules of the farming of twenty centuries—and who knows how much more?—ago, is curious, and at times rather irritating.

It puzzled me for years to understand why the Italian farmer made such a laborious business of the laying out of his grain and grass fields. Whether on stony hill-side or on fertile river-bottom, high on the slopes of the Apennines or on the scorching plains of Campania—in fact, under whatever conditions of soil or climate—I cannot now recall a single instance of grain or grass sown broadcast over a plane surface. On the contrary, after the land is, according to our notions, ready for the seed, it is divided into a series of gently rounded beds. Where space will permit, this is accomplished by means of a plow with double mold-boards, which draws a series of parallel furrows up and down the length of the field. The ordinary width of the beds so made is two or three feet, though in grass-land I have seen them six feet broad, and yesterday I passed a plot of Rye which was growing along prominent ridges about a foot apart, and a very poor show it made. In nine cases out of ten there is no need to assist the surface-drainage by this manoeuvre, and not only would the extra trouble of thus preparing the ground seem worth consideration, but it is a fashion which puts machine-labor in mowing or reaping completely out of the question. I have repeatedly tried to get some clue to this custom from the farmers themselves, but only once have I elicited any other answer than a gently conclusive "Cosi si fa" (it's the custom); and that was when an old man appended, in evident allusion to the degeneracy of our time, that the furrows used to be drawn nearer together. One day, however, I discovered in an ancient manual of farming that the Roman husbandman practiced the self-same fashion, the only difference being that he did so for a reason. His object was to prepare the ground for two crops instead of one, Beans being sown in the furrow as soon as the grain was reaped, and the ridge plowed over them, while the decaying stubble afforded all the dressing that was required in the rich Campanian soil.

The fact is, that the further afield one wanders in this country the more certain he is to be confronted by the ubiquitous ghost of Rome. Halting the other day in an unfrequented little town of Umbria, I saw among the heap of newly forged tools offered for sale by the village blacksmith a spade of a weird, wild shape, much as though a neat crescent had been cut from its blade, leaving two sharp, little horns at the corners. Now, it is obvious that, etymologically, a bidente may be anything with two teeth, from a baby down, and why

may not the Romans term *bidens*, which, under the tuition of men who rarely know one tool from another, we regularly translate mattock, but which seems to have con-noted, as the philosophers say, an immense variety of uses, have been a generic one, covering this sort of thing as well? I do not know what especial end this horned spade may serve, and would not undertake to recommend its introduction; but there is a sort of Titanic trowel, common in this region, which is a joy indeed in the way of transplanting shrubs and taking up autumn roots, for which I venture to bespeak, as for the triangular spade, an impartial trial upon our American soil.

Siena, Italy.

Louise Dodge.

New or Little-known Plants.

Aster amethystinus.

THIS noble Aster appears to have been long an inhabitant of European gardens, where, according to Gray, it is sometimes found growing under the name of *Aster pilosus* and of *Aster Bostoniensis*, although no figure, strangely enough, has ever been published of it. In the gardens of its native country it appears to be less well known, although for many years it has been included in the large collection of native plants successfully cultivated in the Botanic Garden at Cambridge.

Aster amethystinus produces hirsutulous stems sometimes five feet tall or more and widely branched above. It belongs to the *Multiflora* section of the genus as elaborated by Professor Gray, and produces many small racemously arranged heads with spreading herbaceous tips to the imbricated bracts of the involucre, and purple or violet rays. The cauline leaves are small and entire and are sessile, or partially clasp the stem by their bases.

Aster amethystinus (see p. 378) is found growing in low moist ground in Belmont, near Boston, and ranges west to Illinois and Iowa. Like all the perennial American Asters, it is an easy plant to cultivate, growing vigorously and rapidly in good garden-soil, and is easily multiplied by the division of the roots.

Foreign Correspondence.

London Letter.

CALLA PENTLANDII.—This is the second new yellow-flowered *Calla* which has appeared in English collections recently. It was shown in flower at a meeting of the Royal Horticultural Society last month, and it has since been described in the gardening journals as superior to the older *C. Elliottiana*. I believe Mr. Whyte, of Pentland House, Lee, obtained *C. Pentlandii* from a few tubers presented to him two years ago. It flowered in June, and he has since got two offsets from it. He also possesses another plant which, in appearance, is precisely similar to that which flowered. These four plants, the two large and the two offsets, were offered for sale by Messrs. Protheroe & Morris to-day, but did not change hands, although the sum of ninety guineas was bid for them. The extraordinary prices recently paid for these yellow-flowered *Callas* are tempting the Orchid collectors to visit South Africa in search of these and similar plants.

THE BLUE HIMALAYAN POPPY (*Meconopsis Wallichii*) is a beautiful plant in the rock-garden at Kew in July. Planted in deep moist peat-soil, in a position where tall trees afford partial shade in the middle of the day, it grows to a height of five feet, its tall, stout erect stem clothed with silky haired leaves a foot long and numerous axillary racemes of flowers, which expand first at the top of the stem. They are two inches across and of a soft lilac-blue color, paler, no doubt, than they are on the high elevations of the Sikkim Himalaya, but not too pale to be called blue, nor yet too flimsy to be called beautiful. Its home is the home of the Sikkim *Rhododendrons*, and its likes and dislikes in the garden are similar to those of such *Rhododendrons* as *R. ciliatum*, *R. glaucum*, etc. The Poppy ripens seeds freely at Kew, and it takes two years to grow to flowering size. The first year it is kept in a cold frame in pots.

KNIPHOFIA NORTHIIÆ.—This gigantic species of *Kniphofia* was found near Grahamstown and painted by Miss North when on a visit to South Africa in 1883. It was soon afterward introduced to Kew, where it was cultivated in the succulent house along with the *Agaves*, etc., and flowered in 1885. A stock of young plants was raised at Kew from offsets, and these were eventually distributed. Mr. Gumbleton, of Cork, obtained one, which he flowered in July, last year. It has a short, thick stem bearing a huge rosette of glaucous green leaves, four to five feet long, six inches broad at the base, tapering gradually to a long point, keelless, channeled and elegantly recurved. The inflorescence is in the form of a dense raceme nine inches long, on a comparatively short, thick stalk, the flowers an inch long, greenish yellow, the upper ones and buds tinged with red. As a flowering plant this *Kniphofia* is inferior, but as a handsome, really elegant foliage-plant it is worth a place in the garden. A fine example of it is now flowering at Kew, where, notwithstanding the excessive cold of last winter, which killed almost every one of the *Kniphofias* outside, it has stood in a south border against the Orchid house and left unprotected. It is probable that *K. Northiæ* will cross with the handsome flowered kinds. If we could obtain a plant which combined the strikingly handsome habit and largeness of dimensions of *K. Northiæ* with the tall, brilliant-colored flower-spikes of the forms of *K. aloides* (*Uvaria*), and bear the winters, at least, as well as the former, what a grand acquisition it would be. *Kniphofia* breeders, please note. *K. pauciflora* is also in flower at Kew. It is really a free-flowering plant, notwithstanding its name, and it is remarkable in having flowers of a primrose-yellow color. A figure of it prepared from the Kew plant was lately published in the *Gardeners' Chronicle*. The plant is about two feet high, with narrow arching bright green leaves, distinctly ribbed, and without marginal spines. The flowers are in loose racemes on slightly arching scapes two feet high, each flower being an inch long, trumpet-shaped, with exerted stamens. It was introduced to Kew from Natal two years ago and flowered for the first time last March. It is in flower again now. So far it has been treated as a cool greenhouse plant. While writing upon the subject of *Kniphofias* I may mention that there is a new one at Kew which is described as having handsome white flowers.

PTYCHORAPHIS AUGUSTA is a newly introduced Palm from the Andamans, of which there are young plants at Kew. It is not unlike *Cocos Weddelliana* in general appearance, a little more robust, perhaps, when it gets up, but, at any rate, a very likely plant for table-decoration, etc. The genus was created by Beccari for several East Indian Palms allied to *Ptychosperma*, and to include at least one of the *Rhopaloblustas*, of which *R. hexandra* was added to cultivated garden Palms last year. *Ptychoraphis* is easily distinguished by its grooved seeds, resembling those of the genus *Phoenix*. *P. augusta* was described as *Areca augusta* by Kurz in the *Journal of Botany*, 1875, page 332, where it is spoken of as one of the most conspicuous features of the Nicobarese vegetation, pushing its head above the highest forest-trees and forming, as it were, a Palm-forest above the true forest. It has a thin, annulated trunk one hundred feet high, and a head of unarmed pinnate leaves, each twelve feet long, the petiole clothed with short ferruginous scales, and the pinnae a yard long. The tree fruits abundantly every year. A quantity of the seeds have recently been received by and distributed from Kew. Young plants appear to thrive under ordinary stove treatment, and, as they assume an elegant appearance from the earliest stage, they are certain to become popular in the garden.

LILIUM HENRYI is much stronger this year than it was last, and as it has now stood two severe winters at Kew without protection, it may be looked upon as perfectly hardy. It is quite distinct in habit from all other Chinese Lilies; some of the plants at Kew are over six feet high.

It will be remembered that this species was introduced to Kew by Dr. Henry, and that it has yellow flowers as large as those of *L. speciosum* and not unlike them in shape.

PHALÆNOPSIS ARTEMIS is a new hybrid raised by Messrs.

media, which sprung from *P. amabilis* and *P. rosea*, but the flowers of the newer one are larger and of a clearer shade of pink.

CÆLOGYNE SANDERIANA was also shown in flower by

Fig. 63.—*Aster amethystinus*.—See page 377.

J. Veitch & Sons from *P. grandiflora* and *P. rosea*, and exhibited by them in flower at the last meeting of the Royal Horticultural Society. As might have been expected, there is a close resemblance between it and the hybrid *P. inter-*

Messrs. Sander & Co., who introduced a quantity of it about five years ago. It has large, handsome flowers, quite as large as those of *C. cristata*, in drooping racemes, pure white with streaks of chocolate running through the

patch of golden yellow on the lip. It is a first-rate Orchid, but it is not one of the best-behaved under cultivation. The plant shown bore three spikes of ten flowers each.

CALOPOGON PULCHELLUS would be a favorite garden-plant in England if it were less difficult to manage. As it is it is scarcely known to English cultivators, so that a plant of it which was exhibited in flower at the last meeting of the Royal Horticultural Society was looked upon as a novelty and was awarded a first-class certificate. The plant was one and a half feet high and bore a four-flowered spike. Most of the North American Bog-orchids behave badly under cultivation in England. They are all right the first year, but the resting season almost invariably proves too much for them. If there is any "wrinkle" known to American cultivators which would enable us to grow these beautiful little Orchids here there are many who would be most thankful to have that "wrinkle" made generally known. It must, however, be confessed that we fail equally with many of our native Orchids.

Strawberries, Old and New.

THE strawberry season just closed has been a fairly profitable one through this section, growers disposing of their crops at remunerative prices. Owing to the opening of a canning-factory at this place the raising of small fruits has developed to large dimensions, and prices are kept up to paying rates, as there is never a time of glut in the market, and the factory takes the surplus after the local retail market is supplied. The time was when the Crescent was universally grown, but very few of the large growers now find it profitable, although in a few favorable locations it is still the most productive variety. The Warfield, Burt's Seedling, Haverland, Eureka, Bubach and Sharpless are extensively grown, with a sprinkling of Wilsons on some plantations.

On the Station-grounds Burt's Seedling has been the standard of productiveness for the past three years, but failed this year to hold its record, owing to a severe attack of the leaf-blight (*Sphærella Fragariæ*), which disease has been more than usually prevalent the past season, and Beeder Woods took its place at the head of the list, with Greenville, a seedling from Ohio, a good second, and the fruits of which are so much larger and finer in appearance than the Beeder Woods that it is probable that the receipts from the sale of the yields of the two varieties would be in favor of the Greenville. Enhance, a variety grown on the Station-grounds for several years with varied success, has been among the most productive this year, and if the yield could be depended upon it would prove a very valuable fruit, as it is exceedingly high-flavored and very firm. The Van Deman still leads as the best very early variety, the bulk of the crop being harvested when but very few other varieties are in competition with it. It is of more than average productiveness, and on account of its brilliant color and firmness would be a desirable variety even if not early. After two years' trial of Michel's Early the conclusion has been reached that for this section it does not supersede several of the older well-known varieties. While very few of its fruits ripen extremely early, the main crop is about with Crescent, and although its quality is far superior to that variety, its dull color and softness make it inferior from a commercial standpoint. The Parker Earle, which last year proved a grand late variety, was winter-killed quite badly the past season, and in consequence gave only a medium yield. Whether its susceptibility to freezing weather is due to its southern origin or not is impossible to tell, but it is to be hoped that it can be grown through this section, as it certainly is needed for a companion to the Gandy, another fine late variety.

The new-comers tested for one year are some of them valuable, and a brief description of them may be of interest. The Bowman is a perfect flowering variety, with extra large dark green foliage; fruits light red, averaging large; the quality is very fine, but the fruits are too soft for shipment; very similar in flavor to Jersey Queen. Boynton, a perfect variety of vigorous growth, bearing immense clusters of medium-sized dark red fruits of good quality. The Barton is probably the Eclipse of several years ago; the growth of plant is all that could be desired; foliage perfectly healthy; the fruits average large, conical in shape, dark showy red in color, of more than average firmness and fine quality; very satisfac-

tory berry. Feights No. 2, a perfect-flowered seedling, sent here by the originator of the Dayton Early, proves a first-class variety; the growth of plant is very rank; foliage perfectly healthy; fruits large and symmetrical, bright scarlet, and of superb quality; this, without doubt, will become a valuable variety. Feights No. 3, a pistillate companion of the above, gave a larger yield, and the fruits averaged larger than the No. 2, but the color and flavor were lacking. Governor Hoard, a variety of stocky growth; dark green foliage; fruits large and showy, of very fine quality; the plants are above the average in productiveness, and it will undoubtedly become a valuable market variety. The Great Pacific is an Illinois seedling, coming well recommended; its growth is rank; foliage dark green and extra large; the fruits, which are of medium size, are borne in large clusters on stiff fruit-stalks well up in the foliage; berries bright scarlet, very firm, sub-acid; only fairly productive. Gillespie was sent out as a perfect-flowering Haverland; from one year's experience with it we find that, while the plants make a fine growth, it makes but few runners; the fruits are of the same shape as Haverland, with a longer neck; color lighter than the latter; berry very soft and of indifferent quality; yield poor. Hazelton's No. 4, a seedling from Delaware, Ohio, made a very rank growth and furnished a large number of runners; berries only medium size; quite firm and medium tart; yield poor. Hatfield makes a moderate growth; fruits a fair size; flavor a pleasing sub-acid; yield poor. Martha, a pistillate variety of stocky growth, of very dark green foliage; fruits dark red, of only moderate size, but having a very fine flavor; yield about an average crop. Laxton's Noble is one of the most popular English varieties, and deservedly so; growth of plants good; foliage dark green; fruits roundish conical of very dark red color; large and of very fine flavor; its only fault is the very few runners made. Lovett's Early has not proved early here; it is a vigorous-growing variety, bearing a moderate crop of very showy fruit of very good quality, but quite soft; this variety is well spoken of in other localities, and may improve here. Mount Holyoke has some of the characteristics of the James Vick, one of them being its profuse blossoming and its inability to mature over half the berries set; under high culture it may become a productive variety. The Shaw makes a vigorous growth, but does not send out runners freely; the fruits are of good size and very fine flavor. Piper's No. 4, an Illinois seedling, is of low stocky growth, with small dark green leaves, yields but a moderate quantity of conical fruit of medium size and poor quality. Sadie makes a strong growth of light green foliage; fruits are below the average in size, borne in large clusters, bright scarlet; moderately firm; quite tart; does better in stools than in matted rows. Saunders has the same faults as the Shaw, but has larger fruit; a very good garden variety. Woolverton: growth vigorous; fruits of good color, medium size and fine flavor. Walton: of moderate growth; foliage light green; yields only a moderate crop; fruits average small, light red, soft, and of good quality. Walden: this variety makes a very rank growth and matures a fair crop of fruit; berries bright red, very large, moderately firm and of fine quality; a good home berry. Westbrook: of good growth; foliage light green; fruits small, tart, and many of them imperfect. Yale: this variety is of stocky growth, with light green foliage; fruits obtuse-conic, very dark scarlet, with showy yellow seeds; quality fair; season late; this has not proved productive, although it is well spoken of elsewhere. In regard to the Gandy, spoken of earlier in this article, the fact of its being late is but one point in its favor. Here it has been above the average in productiveness. It is one of the handsomest of berries, with its large green hull, perfect shape and handsome color, while the flavor is exquisite enough to tempt few who at the end of a long strawberry season are beginning to tire of even this most delicate of fruits.

Geneva Experiment Station.

C. E. Hunn.

Southern Tomato Blight at the North.

IT is interesting to note that the blight so destructive to the tomato industry in the southern states is doing considerable damage in the north this season. A short time ago Mr. F. L. Stevens sent me specimens of diseased tomatoes from Syracuse, New York. These exhibited manifest symptoms of the southern Tomato blight, and when the central core of the wilted stems was examined it was found swarming with the characteristic bacteria. Laboratory cultures were made of this germ and inoculations of healthy stems were successful in all cases.

Mr. Stevens, at my request, made an inspection of six Tomato fields and found that three were exempt from the blight.

Fig. 64.—A Sugar Maple in Ohio.—See page 375.

Of the others, one had about three per cent. killed, eight per cent. quite badly affected, with many more plants showing traces of the disease. A second field had two per cent. killed, and about two per cent. injured. A third field showed at that time only traces of the blight.

As this trouble is evidently in the northern states it may be well to add that the infested plants first show a wilting as if there was a lack of water-supply, then lose their green color and finally die. The germ is found most abundant in the pith and growing layer of the stem. The blight does not seem to be confined to any particular kind of soil, situation or exposure. It is probable that the plants may be attacked before they are set in the fields, as well as afterward. Potatoes are similarly affected by a bacterium which is communicable to the Tomato, and the germ seems to be the same. In like manner Melons and Cucumbers are attacked by a bacterium, and it is quite likely that they are all the same, and if this be the case, it follows that a soil may become contaminated with bacteria from any one of these crops and make it unfit for any of the others. The Potato, from the nature of its "seed," is the best adapted for the dissemination of the blight, as it can be carried unobserved in the tubers used in planting. Special care should be taken with all land upon which a bacterial disease has flourished. Burn the affected plants when found and also all litter in the field at harvest-time. It is possible that the Bordeaux mixture or some other fungicide may prove effective against this minute and insidious trouble.

Rutgers College.

Byron D. Halsted.

Violet Disease.

THERE is nothing more puzzling to gardeners and florists than the Violet disease, or spot. Its ravages are widespread and unusually fatal to success. The disease seems to attack the plants, and the spores that are dormant germinate more readily when the conditions are most favorable for growth; hence the advisability of getting the plants under cover in frames or houses as soon as excessive day temperatures are past and night dews begin.

In our case failures have been much more conspicuous than successes, and perfectly healthy stock becomes badly infested soon after it is planted in our grounds.

Becoming convinced after repeated trials that starting with healthy plants was not certain to circumvent the disease, we began to try the cure for fungoid growths, as found in the various preparations of copper that are now so generally recommended. Our first trial was made last fall with carbonate of copper and ammonia, and the result was soon apparent; for the foliage perished promptly, either because the mixture was unsuitable on account of the ammonia in it, or the plants were too far gone before the remedy was applied. I think now from added experience that the latter was probably the case.

This spring we started again, with plants from five sources, planted in as many different situations as we could provide. The plants in one of the lots were badly diseased when they came, the others were part clean and part slightly affected; we used the Bordeaux mixture, and soon concluded that it had no curative effect upon diseased plants. It was better to destroy infested plants, root and branch. We have about twenty rows of clean stock planted at right angles to the row that was destroyed, and the half-dozen plants at the end of each row were badly attacked, plainly from being near the others, although all were treated alike with the mixture. All of the above are planted between rows of Celery in a soil that does not dry out readily.

We have also several other lots planted where they are shaded after noon by Elm-trees, but whether in shade or open the disease spots appear. These are dressed before they disfigure the foliage to any extent, so that we do not have to pick off any leaves, as this debilitates the plants and renders the young leaves more liable to attack.

Another point we are satisfied upon is, that the best way to secure good vigorous stock for this year is to avoid using those that were cropped during the past winter to propagate from. The better way is to let the runners grow on a part of the plants, and in fall take them off and make cuttings of them, keeping them in flats all winter, where they will grow the least and yet be free from frost. Of Marie Louise, those so treated are the best we have. It would appear that constantly propagating from plants that have been forced year after year to do their utmost in winter, has so weakened the plants as to render them unable to resist the disease when it appears.

The Lady Campbell Violet, a variety recently imported, is with us less liable to become diseased than the Marie Louise,

though, in time, it will probably be as susceptible as any other. This variety is of a light lavender-blue, similar to the old Neapolitan, but much larger, and produces the sweetest flowers of any Violet. It is sure to become largely grown when better known, for the color is much liked. The kind known locally as the Cape Cod double Violet, and elsewhere as the double Russian, is the darkest blue double Violet—fragrant, perfectly hardy here, but produces its flowers in spring only. When grown in frames it comes in just when the Marie Louise is past, and may always be had in quantity for Easter. The only objection to it is the short stems, but we keep the sashes on most of the time and syringe freely to induce a vigorous leaf-growth, and the flowers will draw up through the foliage. This variety, with The Czar, Schonbrunn, Wellsiana and Victoria (all single), we find disease-proof, and are used when the double kinds fail. The single kinds all produce a crop of flowers, and then stop flowering. The best way is to bring them in from the cold frames in succession, to keep up a supply through the winter. Most Violet-growers have a theory of their own in regard to this disease; but it does not appear to be so well known as it should be that the Bordeaux mixture is a safe preparation to use, and of decided benefit if used as a preventive. As a means of cure it is valueless, if the plants are allowed to become defoliated. There is no better way to treat plants that have lost their leaves than to burn them.

There is also another enemy to Violet-culture in the nematodes, or root-galls, which is harder to deal with than the disease of the leaves. When the plants are so attacked they refuse to grow, and the edges of the leaves have a scorched appearance; the roots are covered with small knots, caused by the nematodes, which are in the soil they grew in, either out-of-doors or on the bench of the greenhouse. To guard against this trouble we have planted the Violets in new soil outside and avoided the use of fertilizers of all kinds, simply adding to the loam a heavy dressing of decayed leaves.

South Lancaster, Mass.

E. O. Orpet.

Chrysanthemums.

CHRYSANTHEMUMS in pots will soon need stimulants in some form. When giving the final potting I leave enough space for a top-dressing in July, and after the roots have fairly used this the feeding process should begin. All will not be in condition to take stimulants at the same time, and no general rule can be laid down. Some varieties are less vigorous than others, and different plants of the same variety vary. Much, too, depends upon the kind of soil used, and whether the plants are potted firmly or loosely. In general, it may be stated that stimulants should not be applied until the plants are well rooted, and should be given sparingly, or withheld from weak varieties or delicate plants. Many of the lessons we have learned by experience in the cultivation of plants under artificial conditions are costly ones, but these are the lessons which are forgotten. Fortunately, there is no plant which will bear so much hard treatment as the Chrysanthemum, and, therefore, I have been able to remedy many mistakes before it has been too late. I had been taught that it was early enough to apply liquid-manure when the flower-buds began to show themselves, and, while I have had good healthy plants grown in this way and fair blooms, I have lost the lower leaves and have never got enough shoots to cover the naked stems. I was convinced, however, that the loss of leaves was owing to the need of nourishment after the pots were filled with roots and must have nearly exhausted the soil. In later years I have applied manures earlier, or as soon as the plants needed additional food. Two years ago some of my plants turned yellow, which I am almost certain was the result of an overdose of guano; but, by allowing them to go as dry as possible with safety and then watering only with clear water, I soon got them into a good color.

Another lesson learned was to pack heavy soil rather lightly, and light soil firmly. A heavy soil packed firmly is always either in danger of getting water-logged, or else the ball dries up so that to get it thoroughly soaked it needs to be placed in a tub of water several hours. This is important to remember when it is intended to feed up plants into large specimens. No rule can be made as to the proper date to commence and proper intervals for feeding. My plants are looking extremely well this season, and the consequence is I am using fewer stimulants. Just now I find the liquid-manure from a stable where three cows and one horse are kept is very satisfactory when diluted with thirty times its bulk of water, and this I only apply once in two weeks. Clay's Fertilizer I find the safest of commercial manures and of good lasting qualities; occasionally I alternate this with guano and some other fertilizer, at the rate of two pounds to one hundred gallons of water. I have

dropped a lump of quick-lime into my manure-tub, but I don't know positively whether it ever did any good.

When there is good drainage and a free open soil, it is perfectly safe and preferable to use highly concentrated manures which contain no solid ingredients to clog the surface as do those impervious mixtures of green cow-manure. I continue feeding until the flowers begin to expand. I have tried it longer, but do not think I gained anything.

Wellesley, Mass.

Hardy Narcissus.

THE time is at hand when Narcissus-bulbs may be transplanted with safety, and often with benefit. The individuals in old-established clumps of these plants are often so cramped for space that only the outside bulbs flower at all, and often when these are lifted and replanted no flowers are produced the next season for the reason that there had not been room enough for the proper development of the flower-buds in the bulb. Some persons have therefore concluded that their bulbs came of poor stock or had deteriorated, but a season of good growth will usually put them in a condition to flower profusely.

Any one who wishes to move bulbs of the Poet's Narcissus, whether of the type *N. Poeticus*, or any of its varieties, should do so as soon as the foliage begins to turn yellow, and not wait, as is best with other kinds, until the leaves have died off completely. The reason for this is simple, and it is important that it should be understood; the fact is, that this Narcissus is never completely at rest, for new roots are produced before the old ones have decayed, and several weeks before the leaves have died down completely. Our bulbs of *N. Poeticus* and its varieties are lifted already, and in a cool airy place, where they are rapidly drying off, when they will be replanted in another situation among grass. The flowers of this section are not desirable for room-decoration in a cut state, owing to their powerful fragrance, consequently they are removed from the border and placed where they will require less attention, and also to make room for the other kinds, most of which have increased threefold in two years from planting.

When planting Narcissus I find it is a great advantage to place at least a handful of coarse sand under the bulb; the difference between bulbs so planted and others planted in the ordinary way is very strongly marked when lifting-time comes. Those planted with sand have not a trace of decay at the base, while others do show symptoms of this dread disease, though there appear no actual losses therefrom, although I was rather apprehensive of danger before taking up the bulbs in our collection of over seventy kinds. When we consider how great are the ravages of this disease in Europe, this is a matter for congratulation, but past experience has led me to the conclusion that the long dry periods we experience during the resting-season of Narcissus is a safeguard against attacks of basil-rot, and that the bulbs will remain perfectly sound if no disturbing element in the shape of decomposing fertilizers be admitted to contact with the bulbs when planted. If the texture of the soil be correct—that is, of a porous nature—then fertilizers can be applied as a top-dressing in fall, when root-action commences, and the rains will wash it down to the roots.

August is the best time to obtain bulbs when new plantings are to be made. Narcissus should be in the ground and making roots about the usual time of purchasing them—that is, when the Dutch bulbs arrive here. There is no reason why we should not obtain Narcissus as early as we do Roman Hyacinths or *Lilium Harrisii*, and dealers would be quick to respond to inquiries for Narcissus were they made at an earlier date than is the custom, and to the purchaser the results would be far better than when planting is delayed until October, for all root-growth is suspended in November on account of frost, before the bulbs have got fairly to work. If late planting must be done, a covering of dry leaves may be put over the beds, and these will keep out any but the most severe frosts almost to the end of the year in ordinary seasons, but this covering must be removed as soon as frost and snow will permit in spring, so that all growth above ground may have light and air. The question may be asked, is it necessary to keep the bulbs out of the soil for any length of time when lifting in summer, as is the custom with English growers at their annual lifting? It will bear repetition, that there is no need of lifting Narcissus annually here, but only for the sake of division. The bulbs, after drying gradually for a few days, may be cleaned of old roots and foliage, separated with care, and replanted at once, since the soil here is warm and usually dry in August, and is, therefore, a better place for storage than we could give them above ground at this season.

Correspondence.

A National Wild Flower Exhibition.

To the Editor of GARDEN AND FOREST:

Sir,—One of the most vivid and pleasing recollections of a recent visit to Scotland is the Wild Flower Exhibition held at Edinburgh. The principal objects of this exhibition are to engage the active energies of the young in a healthful and instructive recreation, and to enlist their sympathies on behalf of their suffering and unfortunate fellow-creatures in children's hospitals. The exhibition at Edinburgh was the fourth one held under the auspices of *The People's Friend*, a juvenile paper. The former exhibits were held in Glasgow, Dundee and Aberdeen. The distinguishing feature of the one just held is, that the exhibits have been entirely gathered by children. In all, there were over 1,700 entries, consisting of hand-bouquets, baskets, bouquets of Heather and Thistles, of Heather and Bluebells, of wild Grasses, of white Heather, of wild Ferns in rustic baskets, wreaths of wild Roses and Honeysuckles, collections of dried wild flowers, and of dried leaves of native trees tastefully mounted, crosses of wild flowers, and window flower-boxes. All, with the exception of the last class, was the work of children. These floral attractions were systematically grouped into various classes and artistically arranged upon tables in Music Hall, where they were subject to leisurely inspection.

The exhibition was opened by Sir William Muir, Principal of the University of Edinburgh, while Mr. John Leng, M. P., acted as Chairman. Upon the platform were many gentlemen of note, including several members of royalty and many of the principal clergymen of the city. Apologies for absence were received from the Duchess of Buccleuch, the Marchioness of Tweed, the Earl of Stair and others, showing the general interest taken in the enterprise.

After calling the large assembly to order, Mr. Leng said, in substance, that Edinburgh was a city of exhibitions. It was regarded, not only by Scotchmen but by all who visited it, as an exhibition in itself. They had floral exhibitions to satiety, representing all the seasons of the year. In the last week they had held a grand horticultural show, but they had never yet had a show like this one, which claimed to be unique, both in its exhibits and in respect to its exhibitors. As a wild flower exhibition it had a character of its own, and he would admit that people generally had little idea that the common wild flowers of the highways and hedges, the meadows, woodlands, hills and mountains, could be set forth with such artistic effect or could produce such a beautiful combination. The exhibition was not local in its character; it did not bring together simply the wild flowers of Mid-Lothian or the east of Scotland; it set before the visitors the entire midsummer wild flora of Scotland from the Shetland Islands to the Borders, and even beyond the Borders, for there were exhibits from England and Ireland as well. The exhibitors of these bouquets and baskets, these devices and decorations, were all children. The flowers had been gathered by their industry and arranged by their skill, so that there were represented before them the results of the labors of nearly two thousand children working with a purpose and a will, that purpose being to help their sick brothers and sisters in the Royal Sick Children's Hospital.

Sir William Muir said he believed that in many respects this would be the most charming exhibition ever held in Edinburgh. Nothing could be more pleasant than to see how the people of the country, especially the children, were interesting themselves in the growing of flowers. It was one of those objects which the public should encourage to the utmost of their power. He trusted that by this flower-show the funds of that most useful hospital, the one devoted to sick children in the city of Edinburgh, would be greatly enlarged, for the institution was well worthy the confidence and support of all interested in the exhibition. The people of Scotland owed an immense debt to Mr. Leng for having originated this idea. The exhibition was then formally declared open. During the day excellent music and dramatic recitals were provided.

The most largely patronized competition was that of the hand-bouquets of wild flowers. In this class there were two sections, junior and senior, with a grand total of no less than 800 entries. One of the principal constituents of these bouquets was the well-known Ox-eye Daisy, while the Dandelion, Poppy, Vetch, Clover, Buttercup, and other species common to the United States, were seen in profusion. The baskets of wild flowers formed very pleasing exhibits. The baskets themselves were usually rustic in character, being made of rushes, willow, bark or some similar material. The flowers in them were usually of the same general character as those in the

hand-bouquets, although many species with short stems were seen in addition. The hand-bouquets of Heather and Thistles were very numerous, and formed a pleasing feature of the exhibition. It was evident that this group appealed most strongly to the nationality of the greater portion of the visitors, and this section of the spacious hall was crowded during the whole period of the exhibition. The native Scotchman lingered proudly among these characteristic plants of "bonnie" Scotland. The bouquets of wild grasses formed another large exhibit, there being upward of 250 entries in this class. The Yorkshire Fog is the common name of a species very largely represented, but in addition to this I observed many tastefully arranged collections consisting in part of Timothy, Red-top, Crab Grass, Meadow Fox-tail, Oat Grass, Orchard Grass, English Blue Grass, Rye Grass, Sheep's Fescue, Couch Grass, Sweet Vernal Grass, etc. The boards of dried leaves of the common British trees formed one of the smaller, but quite attractive, exhibits. It served to corroborate what I had already observed—namely, the comparatively limited number of native species of British trees. The competitors in this class, however, had taken unusual pains with their collections, and they attracted a full measure of attention. In the wild Fern competition the first prize-winner had over thirty species on exhibition. These included several species each of Polypodium, Asplenium, Aspidium, Woodsia, Scolopendrium and other well-known genera.

The exhibit of window flower-boxes did not come up to my expectations, and was, I judge, a disappointment, as far as number of entries was concerned, to the promoters of the exhibition. In varieties, condition and general arrangement the exhibits in this class did credit to the competitors. Among the special exhibits were a small collection of semi-aquatic plants, growing very thriftily in bottles. There was also exhibited a branch of the Forthingall Yew, which is now over 200 years old, and a large collection of home-made rustic flower boxes and stands, some of which were of elaborate design and exquisite workmanship.

The exhibition continued during the afternoons and evenings of two days, the visitors numbering between four and five thousand. The admittance was only six cents, and the total receipts, including the sale of the exhibits at the close, was over \$1,200.

Nearly all the flowers were sold, as those present were glad to purchase some little floral souvenir of the occasion, and knew this to be a simple but effectual method of aiding a cause whose needs are great and whose claims on general sympathy are strong. The expenses of the exhibition were paid by the proprietors of the *People's Friend*, so that every penny that was paid for flowers or at the door went to the hospital.

Edinburgh, Scotland.

William R. Lazenby.

A Tropical Plant-house.

To the Editor of GARDEN AND FOREST:

Sir,—Forty-two years ago, M. H. Simpson, Esq., of Saxonville, Massachusetts, who died a few years ago, built the first greenhouse in this vicinity. Like the one built by H. H. Hunnewell, Esq., of Wellesley, Massachusetts, it was devoted to the culture of grapes. Greenhouses were novelties in those days, and luxuries which very few could afford. Both these houses are of the same pattern, having curved iron roofs, the materials for which were imported from England. Sir Joseph Paxton was in the zenith of his fame then, and these curved iron roofs after his designs were very common. While very substantial, the main objection to setting glass in iron base is the unequal contraction: hence the glass can never be kept close and secure against cold. The original Grape-vines at Saxonville, and at Wellesley too, are yet in bearing. The varieties are nearly the same at both places, and comprise Black Hamburg, Black Prince, White Fontignan, Black Fontignan, Buckland's Sweetwater and Muscat of Alexandria.

A tropical plant-house was the conception of the son, F. E. Simpson, Esq., and was built in 1886, by converting a lean-to Peach-house into a span roof, and adding an ornamental circular end. It is nearly one hundred feet long by thirty wide, with a twenty-feet ridge. The plan is to show tropical plants to the best advantage. Small specimens are grown on low benches along the sides, which allows the use of the entire centre for large specimens. Such an arrangement permits of the disposal of unsightly tubs and pots by plunging them in the ground, while many specimens are planted out entirely, thus giving an opportunity for the proper development of many species which do well in no other way.

Among the many fine specimens the following Palms are noteworthy: *Areca lutescens*, *Cocos Weddeliana*, *Geonoma gracilis*, *Sabal umbraculifera*, *Pritchardia filamentosa* and

Ptychosperma Cunninghamiana. There was a well-developed specimen about six feet high of the handsome foliaged *Sphærogyne latifolia*, with leaves twenty by fifteen inches, and also a smaller specimen of its lovely companion, *Cynophyllum magnificum*. It is admitted by most gardeners as difficult to keep the foliage of these splendid stove-plants free from injury; these under Mr. Hemenway's care, however, are models of perfection. *Dracænas* are evidently more at home here than I have had the fortune to find them elsewhere. Whether the soil, or the water, or the conditions under which they are grown, is the main element of success is a question. Mr. Hemenway thinks it is all owing to a peculiar kind of compressed bog turf, which, it must be admitted, he uses with considerable success with a great variety of plants, including Orchids. A specimen of *Cypripedium Laurencianum*, well in bloom, was exceptionally thrifty. The roots were thoroughly matted through—ample evidence that the plant was at home in the material in which it was growing. Whether it is the soil or not, the conditions for the culture of *Dracænas* were perfect in every other particular—plenty of shade and moisture, equable temperature, all possible in a large structure. *Dracæna fragrans* happened to be in bloom at the time of my visit. The odor filled the house. It resembles Orange-blossom, but is more agreeable, more delicate. This is one of the easiest and quickest growing species and makes elegant specimens up to ten feet, having long, broad, graceful leaves.

D. Knerkii, evidently a variety of *D. Draco*, the Dragon-tree of the Canary Isles, make fine specimens with leaves touching the ground on a specimen eight feet high. *D. Rumpfii* is another which is very distinct; the leaves turn abruptly downward very shortly after being matured. The elegantly variegated form of *D. fragrans*, named *Lindenii*, was in fine condition, the coloring being exceptional for so large a specimen, as it is well known this variety goes "green" after it grows two to three feet high. The collection of *Cordylines*, mostly varieties of *C. terminalis*, is very bright; with the introduction of so many new varieties, many of them scarcely distinguishable from the older sorts, it is difficult to keep them correctly named.

Marantas are perfectly at home here. *M. Zebrina*, one of the oldest and best, measured five feet high from the ground, more than five feet in diameter, with leaves more than two feet long. Other gorgeous specimens were *M. princeps*, a very distinct-looking variety growing about three feet high, with a lighter stripe of green along each side of the midrib. *M. Massangeana*, *M. Makoyana*, *M. pulchella*, *M. Vander Heckii* and *M. virginalis* were among others. *M. Veitchii*, a comparatively rare species, may be compared to a giant *M. Makoyana*, having the same peculiar oblong markings of pale green, showing very distinctly through the dark green and purple shades of the body of the leaf. There were several handsome Aroids, among them an unusually fine specimen of *Phyllotœnium Lindenii*, its large brightly variegated foliage being in marked contrast with the fine, darkly shining leaves of *Alocasia metallica*. *Anthurium Crystallinum* and *A. Warocqueana* were among the collection. *Fittonia Verschaffeltia*, with green leaves and a violet-colored network of veins, and variety *argyroneura*, white, with green network, both in large masses alongside of the paths, made a very appropriate edging, with here and there a pan of *Hoffmannia refulgens*, a curious Rubiaceous plant from South America, with short-jointed creeping stems, thickly clothed with beautifully ribbed brownish egg-shaped leaves about two inches long, which are covered with shining transparent hairs, giving it a peculiar lustre. Scattered among the Palms and other large specimens are many fine tree-ferns, notably *Alsophila australis* and *Cibotium regale*, and also dwarfier-growing species, including *Adiantum formosum*, *A. macrophyllum*, *A. Farleyense* and *A. trapeziforme*. A wall, about ten feet high, on the north side of the tropical plant-house, which separates it from a fernery, is clothed with the common *Ficus repens*, and set in this are elegant brackets for suitable plants and drooping Ferns, and a very pretty effect they make. The wall on the fernery side is covered with a mixture of rough peat and Sphagnum moss held in place with galvanized wire netting. In this are planted various Ferns, *Selaginellas* and numerous *Begonias*, principally belonging to the *Rex* family. The necessary moisture is obtained through a perforated pipe carried along the top, and a very pretty effect it makes. In the house itself is a collection of many species and varieties of *Adiantums*, mostly allied or related to *A. cuneatum*. *A. bellum*, a native of Bermuda, is worthy a special note, its handsome crested foliage being especially striking.

Wellesley, Mass.

T. D. Hatfield.

Notes.

Throughout this month, in the woods and along the country roads, the graceful Clematis Virginiana, with its white star-like blossoms, will convert every unsightly stump and ragged fence into a bower of beauty.

The little Rosa foliolosa of the south-western states should not be omitted in a list of late-flowering Roses. It is of very dwarf habit, and has so far not produced sufficient bloom at the north to be showy.

The American Trumpet Creeper (*Tecoma radicans*) has been in bloom for a fortnight, while its Japanese relative, *T. grandiflora*, is just beginning to open its large showy blossoms. The flowers of *T. grandiflora* are larger in size, richer and purer in color, than those of the native plant (see GARDEN AND FOREST, Vol. iii., p. 393). Both plants are constantly visited by humming-birds through their long blooming season.

On the road from Khandala to the famous Cave of Karli, in India, says Miss North, in her recently published *Recollections of a Happy Life*, she came upon "a splendid tree of *Jonesia Asoka* full of orange-flowers and delicate leaves. The priest of the temple found me one fine flower growing through a honeycomb full of honey, which had been built round its stem. This was a very curious thing." She adds: "Did the buds push their way through the honey and wax, or was the thing built quickly round them? I never satisfied myself which was the first perfected."

In France the common name of the China or Indian Pink (*Dianthus Chinensis*) is likewise "China Pink"; that of the Clove Pink and its offspring, the Carnation (*D. caryophyllus*), is "Florist's Pink," and that of the Sweet William (*D. barbatus*) is "Poet's Pink." Another popular French title for the last-named flower is "Ready-made Bouquet," which is charmingly expressive, and is more musical in French—Bouquet tout fait—than in English. And still another is "Jealousy." Comparing this with "Sweet William," one is tempted to fancy that some ancient story of a love-lorn maid may once have been currently connected with this flower in both France and England.

There is nothing absurd in the idea that the removal of the tassel from Indian Corn should increase the crop, provided enough were allowed to remain to fertilize all the ears. The development of the floral organs of a plant is a great strain on its vitality, and the strength saved might be diverted profitably, it would seem, to the development of the fruit. Experiments on this point, however, have given varying results, and some tests lately made at the Cornell Station show neither loss nor gain in Corn production. It was found, however, that the pollen and anthers in an acre of Corn contained 6.01 pounds of nitrogen, or an amount equal to that in a liberal application of a good commercial fertilizer.

Writing her "Impressions of Alaska" in the June *Bulletin of the Torrey Botanical Club*, Miss Cooley says, with regard to the profusion of berry-bearing plants in the forest-region near Loring: "We found strawberries, salmon-berries, two species of trailing *Rubus*, *R. stellatus* and *R. pedatus*; high blackberries, low blackberries, a raspberry, and four species of gooseberries and currants, all edible; *Sambucus racemosa*, of which the Indians are fond; *Viburnum pauciflorum*; *Vaccinium Myrtillus* and *ovalifolium*; the red blueberry, *V. parvifolium*; the Salal, so highly valued; a pleasant small cranberry and *Vaccinium Vitis-Idæa*, almost as good—enough for man and beast—Klinget and bear and duck. I gathered nineteen of the twenty edible berries which a Chilcat missionary told me are to be found. Of these the salmon-berry, gathered in the summer and preserved for winter use in salmon oil, is most valued. It is a large salmon-colored or orange raspberry, very delicious when picked and eaten fresh from the bushes, though disappointing if bought from the Indians on the wharf, where the aroma of oil that pervades everything Klinget clings to them."

The formal lines of the Maguey plantations, writes Mr. Sylvester Baxter in a recent number of the *American Architect*, running all over the landscape, often as far as the eye can reach, give the country a sort of decorative appearance, but it is too suggestive of tattooing to be picturesque. We use the terms, barren and fertile of aspect, customarily, in an absolute sense, the latter being associated with thick, dark soil and the luxuriance of green meadows and flourishing Corn-fields. Again, certain regions are proverbially known as barren, and their aspect becomes identified with the mental imagery of the word. Cape Cod, for instance, is one of these regions, but in reality the sandy peninsula is one of the most fertile portions

of the country, made so by its Cranberry-culture; swamps, once worthless, now bear hundreds of bushels of cranberries to the acre. So with the thin-soiled peninsula of Yucatan, which annually exports millions of dollars' worth of Henequin, or Sisal Hemp. These dry, wind-swept high plains of the Mexican table-land, bare and brown, desolate and barren as they may look to the stranger, are also wonderfully fertile. Some of these great estates are said to yield net revenues of more than \$100,000 annually, and the two railways, the Mexican and the Inter-oceanic, derive a most lucrative traffic from this region, running special pulque-trains into the capital every morning. The other railway lines also get a considerable traffic in carrying pulque from the capital to regions in the interior where the beverage used to be an unknown luxury.

In a letter contributed to *The Nation*, the organ of the Nationalist party of Ireland, in 1849, Carlyle writes: "Every patriotic Irishman—that is, by hypothesis, almost every Irishman now alive—who would so fain make the dear old country a present of his whole life and self, why does he not, for example, directly after reading this, and choosing a feasible spot, at least plant one tree? That were a small act of self-devotion; small, but feasible. Him such tree will never shelter. Hardly any mortal but could manage that; hardly any mortal, if he were serious in it, but could plant and nourish into growth one tree. Eight million trees before the present generation run out; that were an indubitable acquisition for Ireland, for it is one of the barest, raggedest countries now known; far too ragged a country with patches of beautiful park and fine cultivation, like shreds of bright scarlet on a beggar's clouted coat—a country that stands decidedly in need of shelter, shade and ornamental fringing, look at its landscape when you will. Once, as the old chroniclers write, 'a squirrel (by bending its course a little and taking a longish leap here and there) could have run from Cape Clear to the Giant's Causeway without once touching the ground'; but now eight million trees, and I rather conjecture eight times eight millions, would be very welcome in that part of the Empire." The editor comments upon Carlyle's fundamental unacquaintance with Irish affairs, and points out how hopeless it was to reforest a country where, if a tenant planted his tree or sapling and tended it until it became a mature tree, the law declared it to be the property of the landlord without a scrap of compensation to the man who reared it.

From Mr. Lafcadio Hearn's article, called "In a Japanese Garden," published in the July number of the *Atlantic Monthly*, we quote the following: "The garden contains no large growths. It is paved with blue pebbles, and its centre is occupied by a pondlet, a miniature lake fringed with rare plants, and containing a tiny island, with tiny mountains and dwarf Peach-trees and Pines and Azaleas, some of which are, perhaps, more than a century old, though scarcely more than a foot high. Nevertheless, this work, seen as it was intended to be seen, does not appear to the eye in miniature at all. From a certain angle of the guest-room looking out upon it, the appearance is that of a real lake-shore with a real island beyond it, a stone's-throw away. So cunning the art of the ancient gardener who contrived all this, and who has been sleeping for a hundred years under the Cedars of Gesshoji, that the illusion can be detected only from the zashiki by the presence of an ishidōrō, or stone lamp, upon the island. The size of the ishidōrō betrays the false perspective, and I do not think it was placed there when the garden was made. Here and there at the edge of the pond, and almost level with the water, are placed large flat stones, on which one may either stand or squat, to watch the lacustrine population or to tend the water-plants. There are beautiful Water-lilies, whose bright green leaf-disks float oilily upon the surface (*Nuphar Japonica*), and many Lotus-plants of two kinds, those which bear pink and those which bear pure white flowers. There are Iris-plants growing along the bank, whose blossoms are prismatic violet, and there are various ornamental grasses and ferns and mosses. But the pond is essentially a Lotus-pond; the Lotus-plants make its greatest charm. It is a delight to watch every phase of their marvelous growth, from the first unrolling of the leaf to the fall of the last flower. On rainy days, especially, the Lotus-plants are worth observing. Their great cup-shaped leaves, swaying high above the pond, catch the rain and hold it awhile; but always after the water in the leaf reaches a certain level the stem bends, and empties the leaf with a loud splash, and then straightens again. Rain-water upon a Lotus-leaf is a favorite subject with Japanese metal-workers, and metal-work only can reproduce the effect, for the motion and color of water moving upon the green oleaginous surface are exactly those of quicksilver."

The Pinetum at Wellesley.

THE collection of coniferous trees which Mr. Hunnewell has been forming during the last forty years on his estate at Wellesley, in Massachusetts, is unsurpassed in the number of species and varieties of these trees that it contains, and in the size and beauty of individual specimens. Much has been said and written in the last few months of the injury sustained by conifers in the eastern states during the past winter, which was an exceptionally severe one for these plants; and in order to throw some further light on the subject, we have asked Mr. Hunnewell to furnish us with the dimensions of several of the most important trees in his collection, that our readers may realize the variety of conifers which can be grown in the New England climate, when they are planted in soil suitable to their requirements, and are carefully cultivated.

The soil at Wellesley is admirably suited to conifers, the subsoil being a light porous drift gravel which insures perfect drainage. The surface soil is naturally light loam, but has been enriched and greatly strengthened by the liberal use of peat on which Mr. Hunnewell feeds his plants. They have all received the best cultivation and are generally growing in sheltered positions, so that they have received, on the whole, exceptionally good treatment.

The tallest tree in the collection is a Norway Spruce (*Picea excelsa*), planted as a small nursery plant in 1852; it is now seventy-eight feet high, with a trunk circumference, taken eighteen inches above the ground, of nine feet. A White Pine (*Pinus Strobus*), planted about the same time, is only fifty-six feet high, the trunk girding, at the same distance from the ground, nine feet six inches. *Abies Cephalonica*, planted about 1860, is forty-two feet eight inches high, with a trunk six feet in circumference, eighteen feet from the ground. *Abies Nordmanniana*, planted about

the same time as the last, is forty-two feet in height, the trunk girding only four feet six inches. *Abies concolor* (the California form or *Abies lasiocarpa* of gardens), probably planted about 1870, is twenty-eight feet high, with a trunk four feet in circumference. Another plant of the same species, known as *Abies Parsonsii*, and also Californian, is twenty-eight feet high, with a trunk four feet five inches in circumference, while a third plant, also of California origin, and incorrectly called *Abies grandis*, is twenty-six feet six inches in height, with a trunk four feet seven inches in circumference, all Mr. Hunnewell's trunk measurements being eighteen inches above the ground.

Of the Colorado *Picea pungens*, there are a number of specimens raised from the seed collected by Dr. C. C. Parry, the discoverer of this fine tree in the autumn of 1862. The tallest is thirty-three feet six inches, with a trunk circumference of three feet. A beautiful blue specimen is thirty-one feet high, with a trunk circumference of three feet four inches. *Pseudotsuga taxifolia*, imported from England, and of California or Oregon origin, and planted about 1865, is thirty-six feet high, with a trunk four feet in circumference. This plant grows in an exceptionally sheltered and favorable position, which accounts for the fact of its hardiness, the extreme western form of the Douglas Spruce usually proving too tender to withstand the climate of New England. The largest specimen of the trees of this species raised by Mr. Hunnewell from Colorado seed, collected also in 1862 by Dr. Parry, is now twenty-five feet five inches in height, with a trunk three feet in circumference.

Among other notable specimens, planted about 1870 or subsequently, are plants of the Japanese *Picea Ajanensis* (*Picea Alcoquiana* of gardens), twenty-one feet in height, with a trunk three feet six inches in circumference; *Picea polita*, seventeen feet in height, with a trunk three feet in circumference; *Abies brachyphylla*, twenty-two feet in height, with a trunk four feet in circumference; *Abies Veitchii*, fifteen feet high, with a trunk two feet eight inches in circumference; *Abies Cilicica*, thirty-one feet in height, with a trunk four feet in circumference; *Abies orientalis*, thirty-three feet in height, with a trunk three feet six inches in circumference, and one of the handsomest and most satisfactory trees in the whole collection; *Pinus Koraiensis*, twenty-two feet six inches in height; *Pinus Lambertiana*, eighteen feet in height; *Pseudolarix Kämpferi*, twenty-one feet in height, with a trunk three feet six inches in circumference; *Retinospora obtusa*, twenty-two feet in height; *Retinospora pisifera aurea*, nineteen feet in height; *Retinospora filifera*, fifteen feet six inches in height; the Japanese *Larix leptolepis*, certainly one of the finest specimens, if not the very finest in cultivation, fifty-four feet in height, with a trunk three feet in circumference.

Among smaller specimens, there are fine plants of *Abies Apollinis*, *Tsuga Sieboldii*, *Taxus cuspidata*, from Japan, the best member of the genus for eastern North America, where it is perfectly hardy and very beautiful; *Sciadopitys*, *Thuyopsis dolabrata*, now well established; *Thuya Japonica* (the *Thuyopsis Standishii* of gardens), a hardy tree of much promise; *Picea Omorika*, the newly discovered Spruce of south-eastern Europe; *Abies pectinata*, *Abies Pinsapo*, of doubtful hardiness; *Abies firma*, of Japan; *Abies nobilis*, *Abies magnifica*, and *Abies amabilis*, trees of the Cascade and Sierra Nevada Mountains, which will not thrive in New England unless planted in unexceptionally favorable localities and tended carefully. The collection contains, too, all the well-known forms of *Retinospora*, and many forms and varieties of *Thuya*, *Taxus*, *Tsuga*, etc. The Pinetum proper contains about four hundred specimens, although conifers have been planted outside it in nearly all parts of the estate.

THE Wellesley plantations have a wider interest than that which arises from their dendrological value. The opinion is general that the sole reward of one who plants

trees is a distant hope that some one will enjoy them in after years; that tree-planting is a constant sacrifice of the present for the remote future, and that the highest good a tree-planter can hope to attain is a discipline in the virtues of patience and faith. This view is based on the fundamental error that no tree gives pleasure until it attains its full development, which comes, perhaps, after a century of growth. It would be quite as true to say that parents never enjoy the society of their children until after they become of age. The fact is that the planter finds the keenest delight in the companionship of his trees when they most need his care and are constantly expanding into new beauty under his attention. To the genuine lover of trees the tiniest seedling makes an appeal as direct and personal—though not as strong, of course—as does a Pine or Oak which is crowned with the associations of a century. But even the impatient American, who wants his full-grown forest at once, need not mourn as one without hope. Mr. Hunnewell was approaching middle age when he planted his first trees, and yet they attained stately proportions long ago. They are still improving, and will give increasing pleasure to his successors, but to him they have brought their own reward from day to day and from year to year since the hour when the gardens of Wellesley were planned.

And what a reward it has been! A refreshment from the cares of business that has never for a moment palled or failed—a stimulus for the mind, a wholesome recreation for the body. Hundreds of visitors enjoy the beauties of Wellesley every year, but to none of them are these beauties as fresh as they remain to the man who has created them and has been for years familiar with their changing phases all the season through. In the stress of business-life active men need some diversion, and certainly it is prudent to choose one of which we are not likely to grow weary. Mr. Hunnewell can testify with regard to the one he selected, that he has enjoyed it with a zest and relish that have grown keener every year. Nature is ever young. All her processes are expansive and replete with promise. One whose chosen companions are growing things has found the spirit of perpetual youth, with all its enterprise, exhilaration and hope. There was no selfish thought in the design, nor has there ever been a selfish thought in the maintenance of the Wellesley Gardens. For forty years they have been a public means of instruction and delight, and they will continue to attract visitors as long as there is any appreciation of horticultural taste and skill. But, like all good work, this has not been without its appropriate influence upon the doer—an influence which has helped to give the planter of the Pines of Wellesley the generous enthusiasm, the sunny and hopeful temper, the refinement and simplicity of character which are most thoroughly appreciated by those who know him best.

An Old House in New Jersey.

A RECENT number of this journal (vol. v., p. 367) contained a picture of the house at Morristown well known as the headquarters of Washington during the Revolution. As a companion to this fine example of colonial architecture we give to-day (see page 391) one of the few surviving houses constructed in the earlier, or pioneer, period of New Jersey history. Lyons Farms is just without the suburbs of both Newark and Elizabeth, and although the air vibrates with the roar of two cities this hamlet has been left in an eddy as "improvements" of various kinds have swept by on either side, and it wears an aspect of old-fashioned respectability which is quite in contrast with the upstart suburban smartness which prevails all about it. There are few places in the United States where the old Meeker house would not look out of place, and, to tell the truth, it seems a trifle antiquated even in Lyons Farms. No one knows just when it was built, but its present possessor has evidence that a direct ancestor of his, as well as of the artist who made the drawing here reproduced, was born in it in 1677. It is noteworthy that its present owner

and occupant, Mr. William Grumman, holds it by inheritance, as all its former proprietors have done. The property has never been transferred by deed, but has descended directly from parent to child for seven successive generations from the original Meeker, who held his patent from the Crown.

The roof of the old house has been renewed, but the cedar shingles on the outer walls have remained where they were fastened with curious hand-wrought nails more than two centuries ago to testify to the durability of this wood. They were rived from the trees which once stood on the Newark Meadows—a forest whose remnants are remembered by many men still living. Apparently they never have been painted, but they have not decayed. Weather-worn they are, however, until in many places they are almost scoured away by the action of wind and storm, and the texture of their soft gray fuzzy surface bears little resemblance to that of the original wood. The house is still in fair repair within, and the double doors still swing on the heavy strap-hinges on which they were first hung. Some of the rooms are wainscoted with plank of Tulip-poplar and the heavy beams are scarcely seven feet above the floor.

The surroundings of this relic are quite in keeping with it. The great stone beside the well-curb is hollowed out into an ample basin, in which the family, after the fashion of an elder day, were wont to cleanse their hands and faces in the morning, while the well-sweep, the ancient sun-dial and sundry other details complete a picture which more closely resembles a homestead of the seventeenth century than any other with which we are familiar.

By Bicycle to the Waverley Oaks.—II.

HERE we are with the Waverley Oaks close by. The stream is Beaver Brook, celebrated by Lowell in one of his noblest poems. And now, as when he wrote, "Warm noon brims full the valley's cup." Some people call it Clematis Brook, but the name by which Lowell knew it is preferable. The brook forms the boundary between the town of Belmont and the city of Waltham, and the Oaks are within the limits of the latter place. The Oaks themselves are not conspicuous from the road, but a striking landmark is formed by a gigantic ruined Elm, with a grandeur like that of a crumbling old castle in its decay. It thrusts up its great gray branches out of a dense thicket by the brookside.

Mr. Lorin L. Dame describes this tree in *Typical Elms and Other Trees of Massachusetts*. "At all seasons of the year great trees are good to look upon," he says. "Some are finest when enveloped in clouds of green; others when stripped, like athletes, their mighty arms bared for conflict with the elements. This tree is most impressive in autumn, when its leaves are turned to bright yellow, and the glints of sunlight play upon a trunk of singularly tender color—one of the most poetic grays of the New England landscape."

The place is a typical old New England pasture, with some of the most characteristically beautiful features of such a landscape. We enter on the Waltham side of the brook, leaving our bicycles by the roadside, and stroll along the meandering course of the striking glacial formation known as a "kame," which forms a remarkable geological feature of the locality. Along the base of the kame Beaver Brook flows on its way to the Charles. We soon come upon the Oaks, dispersed over the undulating fields in informal groups, and with the park-like effect that an open sylvan landscape gives. I can do no better than quote Mr. Dame's description:

"The Waverley Oaks are scattered over an area of several acres upon the pasture-land sloping to the brook. Some of them drink of its waters, while others grow upon the sides of the long kame, its most appropriate adornment, 'their deep roots piercing the gravel deposits to the alluvium beneath.' While solitary Oaks as large as these are not uncommon, it is not likely there is another group of such noble trees within the eastern states. With one exception, they are White Oaks, now twenty-five in number. Strength, endurance, fixedness are theirs—sylvan virtues conspicuous even more in winter, when the snow lights up the scarred trunks and the great limbs stand naked against the sky. The sturdy individualism characteristic of the Oak pushes now and then to the verge of eccentricity. Each differs from its fellows; each is worthy the

pencil of the artist; as a whole they admirably illustrate the variant types of the species.

"Southward of the kame the photographer finds a marvelous theme in a shallow pool beset with Asters and tall grasses. At the water's edge, an inverted Oak, the solitary Swamp White Oak (*Q. bicolor*) of the group, stretches downward to an inverted sky. Five feet from the ground it measures twelve feet six inches in circumference; its height is sixty-five feet. Although this Oak, as well as its neighbors, fruits freely, there are no middle-aged or young trees. Were their successors ready to take the place of the falling veterans a part of the fine impressiveness of the scene would be lost. . . .

"It has always been a source of wonder how these trees escaped the ship-builders of Medford, to whom the big Oaks in their vicinity, one after another, fell victims, at a time, too, when the Middlesex Canal was transporting ship-timber that had been floated down the Merrimac from the remote wilds of New Hampshire. It is thought that a dispute with regard to ownership, the details of which are not definitely known, had something to do with their preservation at this critical period.

"The age of these trees, some of them apparently in the full vigor of their maturity, others lightly touched by time, some falling into decrepitude, who shall tell? The trees from time to time prostrated by the wind have been found to be hollow. Agassiz, it is said, roughly estimated the age of one of these at a thousand years. If the rings are to be taken in evidence, a more conclusive judgment is attainable. Some forty-five years ago one of the smaller Oaks was cut down, probably to assert ownership, and the rings, which were counted by Mr. Lowell, numbered over 750. In the light of this revelation Agassiz's estimate comes quite within the range of probability. The largest, and presumably the oldest, of the group may well have sheltered Leif Ericsson beneath its branches, and must have been at its best when Columbus rediscovered America. It stands upon the northern slope of the kame, is about fifty feet high, and measures, five feet from the ground, eighteen feet seven and a half inches in circumference, enlarging to some twenty-eight feet over the swell of the roots. It throws out at broad angles huge irregular branches; one enormous limb, the strength of whose mortising is the architects' wonder, pushes northward more than fifty feet. It was once much longer, perhaps twenty feet, when the mighty trunk, working to its full capacity, sent the life-giving sap to the remotest twigs.

"A huge stump marks the site of a whilom neighbor of this Oak, a great Buttonwood, admired by our fathers. Its prostrate forks still lie along the stream. The old Elm, conspicuous from the highway, is now a picturesque ruin, while the Oak, which has already outlived three or four generations of Buttonwoods and Elms, has in it the promise of decades of life."

These Waverley Oaks have long had a place strong in the affections of the people here, and are a favorite resort for many lovers of nature. The poet Lowell, in particular, was strongly attached to them. The proposition to secure their preservation for public enjoyment dates something like twenty years back. Some of the painters connected with the Boston Art Club then urged their purchase by that institution as a sketching-ground for Boston artists, as Fontainebleau serves for Paris. Fontainebleau, however, is not comparable with the Waverley Oaks in any of the elements of landscape-beauty.

An effort was recently made to secure the place for the Trustees of Public Reservations. The reason assigned by Mr. Dame as probably the one why the Oaks escaped the axe of the Medford ship-builders—a dispute in regard to title—appears to be the true one, since the same reason, fortunate in the first instance, has, unfortunately, prevented their purchase, it having been found that a clear title could not be given to the property. The only hope now appears to lie in exercising the right of eminent domain, and therefore it is felt that in case the Metropolitan Park Commission report a scheme that meets with legislative approval the taking of the Waverley Oaks with certain adjacent features of the landscape should form one of the main elements thereof.

Both in natural features and situation the place is peculiarly well adapted for a public pleasure-ground. It possesses the attractions of remarkable and varied landscape-beauty, scientific interest, both geological and botanical, and the charm of personal association with the memory of a great and noble poet. The population in the neighborhood is increasing rapidly; it lies within the limits of the important factory city of Waltham; Boston and Cambridge are near by, and the two railways running past could, by the establishment of a station, take and leave passengers upon the grounds.

The grand old Oaks, whose frequent dead and naked limbs betray the neglect they are suffering, might, by treatment similar to that which has rejuvenated so many decrepit old trees at

the Arnold Arboretum, be restored to perfect health and assured a vigorous life for centuries to come. The landscape-features of the region are ideal for the creation of a pleasure-ground of rare beauty. The surface contours are beautifully molded, from the meadow coursed by the meandering brook to the fine proportions of the kame, which somehow recalls the modeling of a great sculptor.

Beyond the road to Waltham, which passes above, there rises the stalwartly rounded slope of Helmet Hill, a clean-edged mantle of woodland flung across it beyond, and giving to the grassy portion the effect of a fair shoulder. It would be well to include a portion of this hill, at least, in the park for the sake of the view, which is beautiful and extensive, and, by all means, the land on the other side of Partelo Road, embracing the course of Beaver Brook, as far as, and including, the mill-pond and cascade. This should be done both for the sake of Lowell's memory and for the unsurpassed combination of sylvan and pastoral scenery that would thereby be obtained.

I had never before visited the cascade and did not know exactly where to find it, though aware that it could not be a great distance away. So we determined to follow the course of the brook. This proved no easy task, for the ravine is well wooded, and, besides being rough with granite boulders, moss-grown and slippery in the deep shade, it has a thick undergrowth of the Spice-bush—Snapwood they call it on Cape Cod, because of its very brittle twigs. I remember the copious draughts of "Snapwood-tea" which were given me as a child when I had the measles, for the shrub is deemed an excellent febrifuge, says Gray. As we passed through the thicket the warm, moist air was filled with a very agreeable aromatic odor from the bruised leaves and broken branches.

The musical splashing of falling waters rose above the plaint of the rippling brook as we pressed onward. Soon we found ourselves looking up at the cascade; not a mill-dam, as we expected, but a natural water-fall, the brook tumbling in sturdy, irregular bounds over the same granite ledge that has for ages broken it into a mass of lace-like foam. The mill of Lowell's poem has vanished, with the wheel that tossed "armfuls of diamond and of pearl," and we no longer behold this portion of the picture:

Beneath a bony Buttonwood
The mill's red door lets forth the din;
The whitened miller, dust-imbued,
Flits past the square of dark within.
Swift slips Undine along the race
Unheard, and then, with flashing bound,
Floods the dull wheel with light and grace,
And, laughing, hunts the loath drudge round.

The "busy, never-ceasing burr" has at last ceased for ever. "Sweet Beaver, child of forest still, heaps its small pitcher to the ear," but now it no more "gently waits the miller's will." Hardly a vestige of the mill is now left. For the rest, the place remains as when Lowell described it:

Climbing the loose-piled wall that hems
The road along the mill-pond's brink,
From 'neath the arching Barberry-stems,
My footstep scares the sly chewink.

The high dam itself, as one looks up to it from the cascade, appears a "loose-piled wall," and the comparison of the pretty little pond, placidly snuggling in the woodland, to "a small pitcher" is an apt one.

We found Mill Street running close by, and had we known this fact it would have saved us the toilsome scramble through the thicket. Those readers who wish to visit the place will do well to remember this, and leave the road just after passing a rather modern and prosperous-looking cottage on the left.

The cascade is one of the few in the neighborhood of Boston, and the facility with which it may be included in a glorious park, exceptionally rich in natural features of striking beauty, makes it particularly desirable that the opportunity should be seized. The two portions of the park separated by Partelo Road, including the Oaks and the cascade respectively, could be easily united by raising the road so as to span the brook by a graceful arch, through which a footway might be carried beside the stream and bordering it through the glen to the foot of the cascade.

Boston.

Sylvester Baxter.

"Petty sinuosities and all sharp turns in the course of roads or walks are undesirable; and it should be possible to go from any point in a park to another distant point without excessive indirectness of course; certainly, without so doubling on a course as to produce an impression of a return to the starting-point."

Notes on the Flora of Smythe County, Virginia.
III.

POPULAR tradition declares that the distance from Marion to White Top Summit is twenty-eight miles, and even the most hardened mountaineer calls it the very worst road in the state, and looks upon the ascent of the mountain as an achievement for a lifetime. Most of the residents of Marion took what they called "that 'ere company" for a party of full-fledged lunatics, when they learned that we meditated its ascent a second time, having already spent three nights upon the summit.

Our traveling outfit consisted of two wagons—one fairly strong, drawn by a team of good horses, the other bearing a perilous resemblance to the "deacon's one-hoss shay" toward the close of its magic century. The team, however, was good, though the driver was not a man of brilliant intellect. Neither of the men, born and bred in Marion, had ever been on the mountains, and both would infinitely have preferred to stay at home.

It was on a dull day during the last week in May that we started. The road was passably good till we began the ascent of Iron Mountain, which was crossed at an altitude of over three thousand feet in a driving hail-storm. Along the gap, among the Hemlocks, there was a small grove of White Pine and beautiful thickets of *Rhododendron Catawbiense* intermingled with Mountain Maples (*Acer spicatum*), Striped Maples (*A. Pennsylvanicum*) and great hedges of the luxuriant Purple-flowering Raspberry (*Rubus odoratus*).

The road on the descent of Iron Mountain winds for two or three miles along White Top-tree Creek; the many small brooks that feed it run through dense forests consisting for the most part of Hemlock. Some of the trees are magnificent specimens, three to four feet or even more in diameter, and tower above everything else in the gloomy ravine, where *Rhododendron maximum* made an impenetrable tangle, individual plants being over twenty-five feet in height and tree-like in character. *Kalmia latifolia* was there also in great abundance, quite respectable little trees, with the gnarled, picturesque aspect of old Apple-trees. At that season, however, the only conspicuous tree in flower was *Magnolia Fraseri*. Many of them must have exceeded the fifty feet given as their height in *Gray's Manual*, for in some instances they seemed to rival the giant Hemlocks themselves. These made a picture to be remembered long. All along the gorge the straight, slim Magnolias, their light green leaves glistening with the rain-drops from the sudden shower, stood out in such clear outline against their dark evergreen background that each graceful, perfect flower seemed conscious of its beauty. For several miles at each turn of the road we saw a series of lovely tree-groups, and though, of course, there were many other interesting and remarkable trees, Chestnuts, Maples, Oaks and Tulips, the remembrance is only of the Hemlocks and Magnolias.

At a fork of the road we missed the right turning, and in consequence had to endure six miles, instead of two, of the roughest of corduroy roads; our "one-hoss shay," unlike its famous prototype, breaking down on an average every two hours. We were unable to reach the mountain that night, and took refuge in a small wayside inn near Green Cove on the North Carolina border, some twelve miles by the road from the top.

Near the spring where our hostess kept her milk-pans and great stone jars of butter, we found an antique *Kalmia* that has survived many winters. It was about twenty-five feet tall, and at six inches from the ground measured seven feet and two inches; at one foot from the ground four feet and three inches in circumference. It was not yet in bloom, but its magnificent proportions compelled our admiration.

Among the plants not collected before, nearer Marion, was *Phacelia fimbriata*, with charming little white flowers, a smaller and more delicate species than *P. Purshii*. With it along a little mountain stream was the tiny spring beauty, *Claytonia Caroliniana*, in fruit. The woods were all second growth, and, with few exceptions, large trees were seldom seen. A thousand feet or so below the summit we passed through a belt of Spruce-trees growing in a deep black loam bog. *Clintonia umbellata* grew there in great beds and was at its best; *C. borealis* was just beginning to show its pretty green bells, and unusually large specimens of the yellow Adder's-tongue (*Erythronium Americanum*) were still blooming. *Streptopus roseus*, with its tiny rosy bells, was plentiful; the delicate white *Thalictrum clavatum* grew along every little rill and ditch, as did also a particularly large and handsome swamp form of *Viola cucullata*.

Of all the swamp flowers, however, the most conspicuous and luxuriant was *Anemone trifolia*. This charming little plant, so long confounded with *A. nemorosa*, has rather an interesting history, which has recently been published by Dr. Britton in one of the *Memoirs of the Torrey Club*. It was collected twenty-five years or more ago by Mr. Canby on the Salt Pond Mountain, and again by Mr. Curtiss on the Peaks of Otter. It had been considered a distinct species, but on comparing it with the European *A. trifolia* it was found to be identical, and republished as such. Two years ago we found it in great abundance in flower and fruit in the localities mentioned above, and all through the higher altitudes of the Smythe County mountains we found it this year in even greater quantities, and especially fine in the great swamp on White Top. The plant stands mostly six to eight inches high, and sometimes even higher, and has in every way larger and coarser leaves and larger flowers than the frail little Wood Anemone of the northern lowland woods.

The Spruces were neither very old nor very large trees, and their very ancient appearance was caused by the luxuriance of the moss and lichen crop with which their trunks and branches were covered. Above the Spruce-swamp, on the edge of the road, stood a venerable Birch, one of the remains of the older forest on the mountain—a great gnarled old trunk that measured at three feet from the ground within two inches of twenty-three feet in circumference. Some twenty feet or more from the ground the main trunk was separated into four great erect branches, each a large tree in itself.

Range after range of billowy forest-clad mountain-tops of ever-increasing height, with the Roan and Grandfather mountains for a somewhat hazy background against a cloudless mid-day sky, was the sight that greeted us as we came out of the woods on to the great open field at an altitude of over 5,600 feet. The mountain-slope was not precipitous, but the great semicircle of North Carolina mountains lay apparently just at our feet. The grassy, rocky field, many acres in extent, the grazing-ground of many cattle, spreads right and left of the little group of cabins, where we stayed that night. The actual summit is covered with a dense forest of Black Spruce (*Picea nigra*). The grass is strewn with Violets and little low Strawberry-blossoms, and above, near the trees, the dainty little Carolina *Claytonia* was blooming, while the fragrant Trailing *Arbutus* still lingered in the dense shade. Under the Spruces we walked nearly knee-deep in luxuriant mosses, and the Cryptogamic collection was very large and most interesting. On the topmost cliff *Rhododendron Catawbiense* hardly showed signs of color on its great buds, though along the valleys we had collected and seen it in bloom for a couple of weeks. From those rocks we saw three white-flowered shrubs and trees blooming in the valley below: *Amelanchier Canadensis*, the Service-berry of the natives, its fruit already tinged with red; the Wild Red Cherry (*Prunus Pennsylvanica*), a graceful little tree covered with slender-pedicelled, delicate white blossoms, and the crowning glory of the whole, the Hobble-bush (*Viburnum lantanoides*), its great *Hydrangea*-like creamy cymes shining among the dark evergreens "like a good deed in a naughty world."

Some of the moss-covered boulders were overgrown with clumps of the Fetid Currant (*Ribes prostratum*), a pretty shrub notwithstanding its rather forbidding name, which, however, is well merited.

Early the next day we started on the return trip by a shorter and somewhat better road. On the south-east side of the mountain the white Baneberry (*Actæa alba*), the Blue Cohosh (*Caulophyllum thalictroides*), with strange, inconspicuous little greenish and brownish flowers, and the Umbrella-leaf (*Diphylleia cymosa*) had for a distance complete possession of the woods. The *Diphylleia* is a tall, handsome plant, with large, coarse, roundish peltate leaves and small cymes of white flowers with bright golden-yellow stamens. Along the road two yellow Umbelliferous plants were abundant, the small *Zizia Bebbii*, and the larger, more showy *Thaspium barbinode*. At a somewhat lower altitude we found a thicket of *Menziesia globularis*, with what in the Manual is called *Vaccinium corymbosum*, var. *pallidum*. The Blueberry is a slender shrub, with flat, spreading, very light green leaved branches and very full clusters of greenish white bells. The Pipe-vine (*Aristolochia Siphon*) grew high over shrubs and up on trees, and was covered with its strange little brown flowers.

During the latter part of the descent we were caught in another storm, and reached Marion at nightfall in a drenched condition. The luxuriance and almost abnormal growth of the mountain vegetation are not to be wondered at when the rainfall is taken into consideration. The day without a thunder-storm or sudden, short shower was a rarity, and a three days'

drought happened only once during our six weeks' sojourn in the county.

New York.

Anna Murray Vail.

New or Little-known Plants.

Pterostyrax hispidum.

THE genus *Pterostyrax*, which is now composed of three or four ligneous species of China and Japan, is closely related to our American *Halesias* or *Snowdrop-*

The character of the inflorescence of *Pterostyrax* is shown in the accompanying illustration on this page, made from a photograph of a branch of *Pterostyrax hispidum* which flowered profusely last year in the Arnold Arboretum, where it was introduced several years ago from France, and where in a sheltered situation it has grown into a small tree now ten or twelve feet in height.

Pterostyrax hispidum is quite generally distributed in the northern parts of Japan and in central China where, according to Dr. Henry's notes, it becomes a tree fifty feet in height. The flowers, which are pure white and individually small, are produced in this country from the middle to the end of June.

Foreign Correspondence.

London Letter.

AT the meeting of the Royal Horticultural Society held on Tuesday last (July 26th), there were an unusual number of interesting and new plants exhibited. The bi-monthly meetings of this society have now become the generally recognized "parade-ground" for new and rare plants of all kinds, nurserymen as well as amateurs sending all their new introductions and new productions to be submitted to the various committees. This is as it should be. We now feel certain that every new plant of any promise in England is likely to be sent to these meetings to be judged by the committees and reported upon in the various horticultural papers.

ORCHIDS.—There were some plants of very exceptional interest among the several collections exhibited, the best being from Messrs. Hugh Low & Co., of the Clapton nurseries. *Cattleya Schilleriana*, var. *Lowiana*, is like the type in every respect except the color of the labellum, which is almost wholly of a clear lilac-blue; like that of *Zygopetalum Mackayi*. As a *Cattleya*, it is a plant of more than ordinary interest. *Sobralia Lowii* is a variety of *S. macrantha nana*, with flowers of a rich rosy crimson color. Mr. Norman Cookson exhibited three handsome hybrid *Cypripediums*, namely, *C. Bryan*, raised from *C. lævigatum* and *C. argus*, and resembling *C. Morgania*, except that the petals are shorter and the spots upon them larger; *C. Youngianum superbum*, raised from *C. Veitchii* and *C. lævigatum*, is another hybrid similar in appearance to *C. Morgania*, and is really handsome in the form and color of its flowers; the third one is *C. Tautzianum*, the parents of which were *C. barbatum* and *C. niveum*. It has a large well-formed flower, with broad flat segments, the color pale rosy purple, darker on the labellum.

A spike of *Stauroopsis lissochiloides* (*Vanda Batemannii*), from the gardens of F. Wigan, Esq., of East Sheen, was much admired for its rich colors; it measured two and a half feet in length and bore ten open flowers with as many buds, each flower being two inches across, very fleshy and colored with rich purplish rose on the back, bright citron-yellow in front with brown-red spots, the lip being crimson. Although

Fig. 65.—*Pterostyrax hispidum*.

trees; indeed, Bentham and Hooker, in the *Genera Plantarum*, united the two genera, but we follow Professor Gray in believing that "the terminal paniculate inflorescence, quinary flowers, and thinner, smaller fruit" is sufficient to keep the two genera apart.

not an uncommon Orchid in collections, this plant is only rarely flowered in England. *Dendrobium Leanum*, from the same collection, may be called a variety of *D. Phalænopsis*, with narrower segments than the latter. *Eria vestita* is a rare and handsome Orchid, of which there was a fine example, a yard high, with three stems clothed with leaves from the base upward and bearing five racemes of flowers. The whole plant is clothed with conspicuous reddish hairs, and the flowers are colored flame-red.

Cattleya Rex was shown in flower by two amateurs, and both plants were good. There can be no doubt now of the distinctness of this *Cattleya* from all others. It has the pseudo-bulbs and leaves of *C. Gigas* and a scape six inches long bearing four flowers, the sepals of which are three-fourths of an inch wide, the petals an inch in width, and the lip about the size of that of *C. Percivalliana*, very wavy and crisped; the colors are rich red-brown in the throat, crimson in front, with numerous reticulating lines of gold. The flower is more like that of the rare *C. iricolor* than any other known to me. The Messrs Linden are to be congratulated on having introduced such a distinct and handsome flowered *Cattleya*.

NEMISIA STRUMOSA.—This is a beautiful-flowered Cape annual, which was shown in quantity by Messrs. Sutton & Sons, of Reading. It is a charming plant, less than a foot in height, with lanceolate leaves and terminal heads of flowers, each flower an inch in diameter, and colored almost every shade except blue. This plant was a centre of attraction to gardeners, and was generally voted a first-rate addition to annuals for the open border. *Nemisia* is a genus of about twenty species of South African plants, belonging to the *Scrophulariaceæ*, and allied to *Antirrhinum*; indeed, some of them were once included in that genus. Only two of them have previously been tried in gardens, but they are poor compared with this new-comer, which Messrs. Sutton & Sons have introduced direct from the Cape. It is very remarkable in the wide range of color in its flowers.

CRINUM SANDERIANUM is a very handsome stove-plant, and apparently an easy one to cultivate. It was introduced by Messrs. F. Sander & Co. in 1884 from Sierra Leone, and described by Mr. Baker. It is a close ally of *C. scabrum*, a common plant in tropical Africa, and *C. Kirkii*, a fairly recent introduction from eastern Africa. These are all large-bulbed, with short necks, glossy deep green leaves and erect scapes from one to two feet high, bearing umbels of from four to six flowers. In *C. Sanderianum* the flowers are large, with a curved tube six inches long, and broad lanceolate-connivent white segments, colored deep red along the midrib or keel. A plant of this *Crinum* has lately been an attraction in the stove at Kew. *C. Americanum*, a handsome species from the southern United States, is also in flower. It is a first-rate plant for beds in large stoves; at any rate it has stood in a bed in the Palm-house at Kew for the last ten years, and has flowered annually. It has an erect scape two feet high, bearing an umbel of four white flowers with narrow spreading segments and very fragrant. *C. Moorei* is at its best in the conservatory, and *C. capense* is in full flower in the borders outside.

HÆMANTHUS KATHERINE is a very handsome stove bulbous plant, and as easy to cultivate as the *Eucharis*. It is scarcely known in gardens, notwithstanding the enormous size and rich colors of its flower-heads, and the fact that it was introduced from Natal in 1877 and is easily propagated by means of offsets and seeds. Growers of bulbs for the European and American markets might do worse than plant largely of this *Hæmanthus*, the finest by far of all the species known.

GLOXINIAS.—Messrs. Sutton & Sons are the possessors of an extra-large flowered and otherwise attractive strain of these plants. They exhibited two named kinds at the last meeting of the Royal Horticultural Society which were favorably noticed, their names being: Her Majesty, with erect, very large, pure white flowers, the finest white yet seen; Duke of York, also erect, very large and white out-

side, deep crimson inside, with a broad, well-defined margin of pure white. They also sent some prettily reticulated varieties.

MR. ECKFORD'S SWEET PEAS were a charming exhibit. I noted four of the best, which are: Emily Eckford, rich violet; Blanche Burpee, pure white; Peach-blossom, rich blush-rose, and Ovid, rosy crimson. Another noteworthy one was named Stanley, the flowers of which were deep vinous purple, almost too dark in fact. I believe these named Sweet Peas come true to color from seed. Mr. Eckford supplies them in sealed packets at from a shilling to half-a-crown a packet. Mr. H. Cannell exhibited a collection of his large double-flowered *Begonias*, arranged in a novel manner, each flower being mounted with *Adiantum* and *Asparagus*, and forming a really pretty button-hole bouquet. A lecture by Mr. A. J. Manda, of the United States Nursery, Hextable, on insectivorous plants, was the means of bringing to the meeting several fine collections, comprising *Nepenthes*, *Sarracenias*, *Droseras*, etc. Mr. Manda himself staged a very creditable group of small specimens, and the *Nepenthes* from Messrs. Veitch & Sons were exceedingly good, the cream of them being *N. Burkei* and its variety *excellens*, *N. Curtisii*, and, of course, *N. Mastersiana*, which still retains premier position among cultivated *Nepenthes*.

CARNATIONS.—A special exhibition of these was held at the Drill Hall last Tuesday, and was a great success, the flowers, generally, being above the average, while the plants were mostly good in foliage and flower. The best Carnation in the whole show was Dr. Hogg, exhibited by Mr. C. Turner, of Slough, and the best Picotee, Mr. Douglas's Favorite. Mr. Turner's first prize collection of plants in flower comprised the following: Romulus, Iona, Mrs. L. Jamieson, C. Henwood, King of Scarlets, Duchess of Sutherland, Ruby, Favorite, Mr. Clements, Victory and Mrs. Nicholay. Mr. Douglas also took first prize for twelve trusses of one kind of Carnation with *Oriflamme*, a seedling border Carnation with large full flowers of a rich carmine-red color, in my opinion the most meritorious garden-plant in the whole lot. Another beautiful border Carnation is Colin de Haselvillo, with rich scarlet full flowers on stout stalks. Our exhibitions of florists' flowers are often spoiled by old-fashioned fads. A Carnation is a beautiful flower, seen at its best when on the plant and supported only by the ordinary stake and bast-tie, but it is a miserable object seen at its worst, cut and laid out on a disk of white paper and deprived of half its petals, the remaining half being arranged regularly and flattened out. And yet the latter is the recognized way to set up a Carnation-flower to be judged and admired. These dressed and collared flowers are worthless to every one except the florist showman; they are not Carnation-flowers at all in fact, and a bunch of natural flowers direct from the plants is worth a bushel of such "faked" productions.

Notes on Shrubs.

THERE are several species of midsummer-flowering *Clematis*, distinct from the large-blossomed Florida or Jackmanni types, which, although long known to cultivators, are not very often met with in American gardens. The large-flowered and very showy species are now well disseminated and the older varieties advertise themselves. It has not taken many years to make almost every amateur gardener in the land familiar with such a plant as *C. Jackmanni*.

Some smaller-flowered species and varieties with colored flowers are in a manner quite as interesting as their more showy congeners, and are well worth more general cultivation in our gardens. *C. Viticella* is probably better known than most of them, but it is quite uncommon here. Although a slender-looking vine, it grows freely and tall, and will thickly cover a pillar or trellis or low wall with light graceful foliage, and with flowers nearly two inches in diameter, which expand most abundantly from about the end of June until the end of July. The flowers are ordinarily of a reddish purple color,

the outside being paler. They are not appreciably fragrant. There are a number of forms with variations in the color of the flowers, some of them being quite pale, or the sepals may be dark on the outer ends, changing to almost white at the base, and there are one or two forms which have double flowers. There are not many kinds of *Clematis* with colored blossoms which bear flowers in greater profusion, and it is perfectly hardy in this climate without any protection.

A very pretty and interesting little sub-shrubby species is known to botanists as *C. aromatica*, although it is probably more generally known in nurseries and gardens under the name of *C. cœrulea odorata*. It is not a climber, the stems only attaining a height of four or five feet, but requires a slight support in order to keep in an erect position. The flowers are a couple of inches across, the four sepals of a rich dark purple color, even darker than the great flowers of *C. Jackmanni*, and they have a sweet delicate odor. The sepals are narrow, becoming much reflexed after full expansion of the flower. The stamens are white, long and freely spreading. The plant seems quite hardy here, flowers freely from the latter part of June until the end of July—there are still a few stray flowers (August 3d)—and it requires the same treat-

in best bloom during July, but which differ from the foregoing species in having flowers which do not expand their sepals widely, but are narrowly inversely bell-shaped or vase-shaped. Although natives of our own country they are extremely rare in our gardens, the large-flowering showy sorts receiving almost all attention. These American species, while not brilliantly showy like the others, are extremely interesting, and some of them bear very pretty flowers.

Clematis coccinea is one of the most curious as well as one of the most attractive of them all. A native of Texas and the south-west, there seems to be no question of its hardiness here if given a warm well-drained soil, but it does not show the vigor and tenacity of life of some other species. Its flowers are almost top-shaped, or inversely bell-shaped, with the tips of the sepals only spreading slightly and forming a very small mouth. The color of the outside, which is perfectly smooth, is a bright red or scarlet, the small exposed interior portion light yellowish. The sepals are so thick and fleshy that they suggest edibility, but they are spongy and almost tasteless. The stems of the plant ordinarily grow about five or six feet in height.

Clematis crispa grows somewhat larger, and its sepals ex-

Fig. 66.—The Old Meeker House at Lyons Farms, New Jersey.—See page 386.

ment as other sub-shrubby or herbaceous species like *C. recta*. It is curious that the native country of this *Clematis* is unknown.

Another desirable species of much the same habit, but of somewhat larger, stronger growth, and which blossoms during about the same season, is known to us as *C. Eriostemon*. It has deep blue-purple flowers about two and a half inches across, composed of four thick strongly nerved sepals, which spread into a broad bell-shape, not becoming quite horizontal. The blossoms have a slightly sweet fragrance and are produced in abundance singly on long stalks, and when in good condition the plant is quite showy and attractive. It is perfectly hardy without any special care or protection, and is well worth more general use than it now enjoys. Wherever it is cultivated it is probably better known under the garden name of *C. Hendersoni*, while *C. Chandleri* is also said to be another synonym. Some years ago the Arboretum received a very pretty form from Herr Max Leichtlin, labeled *C. Eriostemon Spachiana*. This bears pinkish purple or very pale magenta colored flowers, the color deepening toward the base of the sepals.

We have several hardy native American species, which are

pand and recurve much more than those of the last species. Its flowers are very markedly ribbed on the outside, and they are of a very pretty pale lilac or light purple color. Its sepals are much thinner than those of the other.

These two kinds are the most beautiful and best deserving of cultivation among these peculiar American species. Several others are interesting, though not generally so pretty or so much admired.

Clematis Viorna, the so-called Leather-flower, with reddish purple blossoms, is well worth cultivating with the others, while *C. Pitcheri* will prove one of the most vigorous plants of all. The flowers of this are usually large and of a dull purplish color, the inner side of the sepals being very dark. It is a free-blooming species, but not showily ornamental. It appears to vary considerably in the size and depth of color of the flowers on different plants. Lavallée, in his celebrated monograph, described as *C. Sargentii* a plant which appears to be only an extreme form of *C. Pitcheri*, having small flowers and unimportant modifications in the leaves.

Arnold Arboretum.

J. G. Jack.

Cape Oxalis.—I.

THE greater part of the winter-blooming Oxalis now in cultivation are natives of the Cape of Good Hope, whence most of them were introduced a century ago, principally by Masson. In this article I wish to describe a group of species and varieties characterized by showy and generally large flowers and by glossy black bulbs, which are coated, inside the outer skin, with a sticky black matter and taper to a sharp point at each extremity, so that root-end and stem-end are indistinguishable from each other in a dormant bulb. How many of these forms are true species I am not botanist enough to decide, though it is very plain to those who have observed them under cultivation that some which are known by distinct names are but varieties of the same type.

Probably the best known of this group is *Oxalis versicolor*, which is a very beautiful little species with tufts of small leaves, each composed of three narrow leaflets, from among which rise the flowers on stems long enough to raise them well out of the foliage. These are about as large as a dime, pure white on the inner face (except the yellow of the throat, common to nearly all species of the genus) and striped with crimson on the outer edge of the back of each petal. When the flower is in bud this edging appears as a crimson spiral, and greatly enhances the attractiveness of the plant. In this description I have had in mind the best form of the species, for there are two other inferior varieties (given as species by Jacquin), *Elongata* and *Tenuifolia*. It is the last-named which is generally sold as *Versicolor*; its flowers are much smaller than those of the type, and their petals are narrow instead of broad; the leaves are smaller and of a darker color. I could get nothing but this from many different sources, and at last obtained the type, some eight years ago, from Van Houtte's nursery. I do not know where it can now be found. The variety *Elongata* is a trifle larger in flower than the type, but, as the crimson edging is absent or nearly so, it is less attractive. It is, of course, well known that many other species are marked with red exteriorly, but in *Versicolor* alone is this marking brilliant enough to be ornamental.

Oxalis variabilis, in all its forms, is one of the most pleasing species. Its leaflets are broad, of a deep green often of a bluish cast, and its flowers, when well grown, are an inch and a half in diameter. Jacquin gives the white form as the type, though his figure seems to represent the white variety of *O. purpurea*. The white *Variabilis*, which I am sorry to say I have lost, is perfectly pure in color and appears in profusion all through the winter. *Variabilis rubra* also blooms abundantly for many months; its color is very bright and fresh, very unlike that of Jacquin's plate. A difference between these varieties is that the leaflets of *Rubra* have very few, if any, fringing hairs, while *Alba* had, as I remember it, very many. I have two other varieties, *Simsii* and *Longiscapa*, red-flowered kinds of no particular interest.

Oxalis grandiflora was made a species distinct from *Variabilis* by Jacquin on account of the redness of the under side of the leaflets, which in *O. variabilis* is green, but I do not find this redness constant. Yet there are differences evident enough in the growing plants, for the flower-stalks of *O. grandiflora* are longer than in *O. variabilis*, and the flowers have less substance; there is a difference also in the color of the leaves.

Oxalis purpurea is a fine species with several good varieties. Its general aspect is much like that of *O. variabilis*, but it is of somewhat larger growth, its flowers being often over two inches across, especially in the type. Jacquin's figure gives the color as intense red-purple, approaching crimson-lake, but it is not so. A somewhat bluish purple is the true tint. Its variety *Laxula* differs from the type by its vivid crimson leaf and flower-stalks, which add much to its beauty. The variety *Alba* is the largest white-flowered kind, but its white is somewhat tinged with purple. This is a very handsome kind. *Rosea* and *Lilacina* are varieties whose distinctive color is expressed by their names. The species *Laxula* figured by Jacquin, a white-flowered kind which he thinks may be a variety of *Purpurea*, is unknown to me.

Oxalis breviscapa, which I had for a few years, and which I lost by that pest of small-bulb growers, mice, is a very interesting kind by reason of the shortness of the flower-stalks and the bright tan-colored under sides of the leaflets, two features which give the plant an unusual appearance. *Rigidula* is another very pretty white-flowered kind.

There are several other species belonging to this group of which I will say nothing because I have not yet been able to obtain them.

Like other Cape bulbs, all species of *Oxalis* can be carried safely through the winter in a cold frame; but the species named in

this paper (except *O. versicolor*) are the hardiest of all, since they cannot only be planted out-of-doors in October, with a slight covering of leaves, with perfect security, as can several other species, but they will then bloom profusely in May, as other kinds will not do. It is best, however, to grow them as pot-plants, for we are apt to forget small things in the open ground, and a few days of great heat and dryness speedily destroy the little plants. Rather let them be potted, about six in a six-inch pot, at the end of summer, and be put in a sunny place indoors; then, with proper attention, such as house-plants usually have, they will be beautiful until spring. I hope hereafter to write of some of the other species with which I have had experience.

Canton, Mass.

W. E. Endicott.

Notes on Stove-plants.

MEDINILLA MAGNIFICA.—This handsome species makes a valuable addition to any collection of stove-flowering plants in which large specimens are admissible, and, though not by any means a new plant, is still uncommon enough to attract much attention when exhibited. *M. magnifica* is a strong-growing plant of shrubby habit, with large ovate leaves, the latter being dark green and of somewhat leathery texture. The flowers are produced in pendulous racemes from the tips of well-ripened growth, and are rose-pink, the upper portion of the raceme being also more or less clothed with pink bracts, which add much to its showiness. To secure a good result from this plant it should be grown under similar conditions to those furnished to *Ixoras*—that is, plenty of heat and moisture during the growing season, and a somewhat less amount in winter, the flowers usually appearing in spring or early summer. Propagation by cuttings is not difficult, providing the wood used for the purpose is not too hard, single-eye cuttings being a good method to use in the operation.

RUDGEA MACROPHYLLA.—This is another strong-growing stove-plant, and also long in cultivation, but seems even more uncommon than the *Medinilla*, to which it is a good companion plant to the above, thriving under the same treatment. It is also an erect-growing shrub, and has large oblong-ovate leaves on which the veins are quite prominent; the flowers are cream-colored and are produced in dense erect panicles from the tips of the shoots. *Rudgea* is also propagated by means of cuttings, which root in a reasonable time if placed in a warm propagating-frame. The best soil for either of the above plants is a light loam, well drained, and enriched with some old manure, but if the only available loam is of a clayey character it is best to mix some peat and sand with it in order to make a more open soil.

PAVETTA BORBONICA.—This is another unusual plant in the average collection, though well deserving to be more widely known, and is said to be related to the *Ixoras*, though grown for its handsome foliage rather than its flowers. The leaves of *P. Borbonica* are opposite, from six to ten inches long and two to four broad, their ground color being olive-green, on which the yellowish white spots appear to advantage, while the midrib is reddish. The leaves of this plant are glossy and very attractive, especially when it is grown in a single-stemmed plant to a height of two feet or more, and well furnished with foliage. A high temperature is best for *Pavetta*, with abundant moisture, and, in order to secure the best coloring of the foliage, abundant light should be given. A mixture consisting of two-thirds loam to one-third peat and some sand makes a satisfactory compost, and the pots should be well drained. It is propagated by cuttings, which should be placed in light peaty soil in a rather close propagating-frame, but even under the most favorable circumstances these cuttings will take a considerable time to root, perhaps from two to three months.

Holmesburg, Pa.

W. H. Taplin.

Euphorbia pulcherrima.

UNDER its garden name of *Poinsettia pulcherrima*, this very showy winter-flowering plant has long been known and valued by many growers, but it must be admitted that so striking a subject deserves even wider distribution. Since the introduction of various forms of this species the time of flowering has been much extended, so that with proper management the blossoming-season can be prolonged from November to April, thus giving a supply of these brilliantly colored bracts during the whole of the dullest season of the year. As already intimated, it is in the bracts surrounding the true flowers of *Euphorbia pulcherrima* that the special beauty of this plant is found, and in well-grown specimens the head of such bracts attains a diameter of twenty to twenty-four inches,

and becomes a truly dazzling mass of scarlet. In order to secure such results generous treatment is necessary, and should be begun early in the summer. Care should be taken that the plants do not become dry, and they should be shifted on as the roots require it. The soil should be a rich light loam, in which a liberal allowance of dry cow-manure should be mixed, and after repotting the plants should be carefully watered for a week or two until the roots take hold of the new soil.

During the summer *E. pulcherrima* may be stood outdoors, this inducing a more stocky growth, but I think it advisable to place the plants in such a location that they can be covered with some sashes during rainy weather, for, when exposed to too much rain, they are apt to lose the lower foliage, and a long naked stem is no addition to their beauty. Some growers adopt the less troublesome plan of planting *Euphorbias* out in the open ground during the summer, but one great objection to this method is found in the fact that they do not lift well, the growth being soft and sappy, and, consequently, much foliage is lost in the operation if the weather should prove unfavorable. But, whatever method be adopted, it is not wise to allow these plants to remain outdoors after the nights become cool in the fall, for they are quite susceptible to cold, and a check of that character will result in smaller bracts.

After blooming, the old plants may be laid away under the benches in a warm house, and they will not require any water until it is time to start them into growth again in the spring, when they should be pruned back hard, and shaken out before repotting. Cuttings may be made of the old wood secured at the time of pruning, or from young shoots from three to six inches long, taken off with a heel of harder wood attached, the latter placed in a close propagating-frame and carefully protected from the sun, and they will with proper attention soon make roots. The young plants secured by the latter method will make a useful size for conservatory decoration during the following winter, providing they are potted on when necessary.

In addition to the type there is a double-bracted form of this plant known as *E. pulcherrima plenissima*, the whole centre of which is filled up with a crowded mass of smaller bracts of similar color to the original species. The form in question, one of the discoveries of the veteran collector, Mr. B. Roezel, created quite an excitement in the horticultural world at the time of its introduction, between fifteen and twenty years ago. The bracts of the double form are more lasting than those of the type, and, if water is not allowed to collect in the flower-heads, they may be kept in good condition on the plants for fully two months.

Another handsome variety is *E. pulcherrima major* (also known as *E. rosea carminata*), in which the bracts are of medium size and of a pleasing shade of carmine. There is also a variety with white bracts, but this is inclined to be weedy-looking, and is but little grown at the present time.

Philadelphia, Pa.

H.

Coreopsis monstrosus, sent out recently by a Continental nurseryman, proves to be an improved form of what is usually known in gardens as *C. lanceolata*, but which is correctly *C. grandiflora*. The foliage is identical, and the variety is a very vigorous grower, a small specimen received early in the year forming now a large plant. The flowers are of a deep yellow, and somewhat larger than the type. The individual petals are very broad, from three-fourths to seven-eighths of an inch broad. As compared with other plants which represent the best hitherto attainable, the *Monstrosus* is distinctly an improvement. It seeds freely, but probably it will be necessary to propagate it by root-cuttings or side-shoots as usual.

Carnation Cyclops.—A few years ago a French nurseryman offered a strain of seed under the name of *Dianthus plumarius hybridus*, said to be a cross between *D. plumarius* and a Remontant Carnation. Plants from these proved to be very hardy, and were furnished with single flowers of an unattractive dull magenta. The strain offered as *C. Cyclops* seems to be a similar cross with a wider range of colors, some of which are pleasing, and it bids fair to be a useful plant for the garden. Double-flowering kinds were also offered, but these were not experimented with. The seeds of these germinated very strongly, in marked contrast with the Redondo Carnations offered by H. A. Dreer. These are said to have originated in California. The plants have very glaucous Carnation-like leaves, and there seems to be a great range of form and coloring among the flowers which are now showing. As they are very fragrant, come into flower the first season, and many of them are double and of good color, this strain seems to be worthy of further trial.

Elizabeth, N. J.

G.

The Forest.

Forestry in Prussia.

IN former numbers we have quoted extracts from a chapter on the "Woods of Minnesota," prepared by Mr. H. B. Ayres for the last volume of the Geological Survey of that state. Another portion of the same admirable paper includes some observations of Mr. Gifford Pinchot on Forestry in Prussia, which we reproduce below :

"All forest-management may be said to rest on two closely related facts which are so self-evident that they might almost be called axioms of forestry, but which, like other axioms, lead to conclusions of far-reaching application. These are, first, that trees require many years to reach merchantable size; and, secondly, that a forest-crop cannot be taken every year from the same land. From the last statement it follows that a definite far-seeing plan is necessary for the rational management of any forest, from the first; that forest-property is safest under the supervision of some imperishable guardian, or, in other words, of the state."

"Holding it as a duty to preserve the woodlands for the present share which they take in the economy of the nation, the state has recognized as well the obligation to hand down its forest-wealth unimpaired to future generations. It has recognized and respected equally the place which the forest holds in relation to agriculture and in the economy of nature, and hence feels itself doubly bound to protect its woodlands. In a word, it has been seen that in its direct and indirect influence the forest plays a most important part in the story of human progress, and that the advance of civilization only serves to make it more indispensable."

It has, therefore, steadily refused to deliver its forests to more or less speedy destruction by allowing them to pass into the hands of shorter-lived and less provident owners.

Even in the times of the greatest financial difficulty, when Prussia was overrun and nearly annihilated by the French, the idea of selling the state forests was never seriously entertained.

But the Government of Prussia has not stopped here. Protection standing alone is irrational and incomplete. The cases where a forest reaches its highest usefulness by simply existing are rare. The immense capital which the state woodlands represent is not permitted to lie idle, and the forest, as a timber producer, has taken its place among the permanent features of the land. The Government has done the only wise thing by managing its own forests through its own forest-officers.

"Donner, now Overland Förstmeister, in a work which carries all the weight of an official document, says:

"The fundamental rules for the management of state forests are these: First, to keep rigidly within the bounds of conservative treatment; and secondly, to attain, consistently with such treatment, the greatest output of most useful products in the shortest time."

"The state believes itself bound, in the administration of its forests, to keep in view the common good of the people, and that as well with respect to the lasting satisfaction of the demand for timber and other forest-produce, as to the numerous other purposes which the forest serves. It holds fast the duty to treat the Government woodlands as a trust held for the nation as a whole, to the end that it may enjoy for the present the highest satisfaction of its needs for forest-produce and the protection which the forest gives, and for all future time, at least an equal share of equal blessings."

"The forest is a trust handed down from former times, whose value lies not only in its immediate production of wood, but also essentially in the benefit to agriculture of its immediate influence on climate, weather-protections in various ways, the conservation of the soil, etc. The forest has significance not only for the present nor for its owner alone; it has significance as well for the future and for the whole of the people."

"With respect to the second class of forest-property, that belonging to towns, villages and other public bodies, it is again impossible to speak for the whole of Germany except upon the broadest lines. The state everywhere exercises oversight and a degree of control over the management of these forests, but the sphere of its action varies within very wide limits. Even within the individual states it does not remain the same. Thus far, however, the action of the Government is alike, not only throughout Prussia, but in all parts of Germany. It prevents absolutely the treatment of any forest of this class under improvident or wasteful methods; nor does it allow any measure to be carried into effect which

may deprive posterity of the enjoyment which it has a right to expect."

"The relations of the state to the third class of forests, those belonging to private proprietors, are of a much less intimate nature. The basis of these relations is, however, the same. To quote again from Donner: 'The duty of the state to sustain and further the well-being of its citizens, regarded as an imperishable whole, implies for the Government the right and the duty to subject the management of all forests to its inspection and control.' This intervention is to be carried, however, 'only so far as may be necessary to obviate the dangers which an unrestrained utilization of the forest by its owners threatens to excite, and the rights of property are to be respected to the utmost consistency with such a result.' Prussia, of all the German countries, has respected these rights most highly, and the Government exerts practically no restraining influence except where the evident results of deforestation would be seriously dangerous. Here it may, and does, guard most zealously the woodlands, whose presence is a necessary safeguard against certain of the more destructive phenomena of nature, and which have been called in general 'protection forests.' Of their many-sided influence so much has been said and written of late in America—both truly and falsely—that no further reference to the subject seems needful.

"The state leaves open a way of escape for the private proprietor who finds himself unwilling to suffer such restriction of his rights for the public good, and shows itself willing to buy up areas not only of protection forests but also of less vitally important woodlands. On the other hand, it is ready, with a broadness of view which the zeal of forest-authorities sometimes unfortunately excludes, to give up to private ownership lands which, by reason of their soil and situation, will contribute better to the commonwealth under cultivation than as forest.

"In this way the forests, whose preservation is most important, are gradually passing into the hands of the state; yet the total area of the woodlands is increasing but slowly.

"The policy of state aid in the afforestation of waste lands important through their situation on high ground or otherwise is fully recognized (a notable example exists upon the Hohe Venn, near Aix-la-Chapelle), but the absence of considerable mountain-chains has given to this branch of Government influence very much less prominence than in the Alps of Austria, Switzerland and France, where its advantages appear on a larger and more striking scale.

"In closing this brief sketch of forest-policy in Prussia, you will perhaps allow me to refer for a moment to the erroneous ideas of German forest-management which have crept into our literature. They have done so, I believe, partly through a desire of the advocates of forestry to prove too much, and they injure the cause of forestry, because they tend to make forest-management ridiculous in the eyes of our citizens. The idea has risen that German methods are exaggeratedly artificial and complicated, and not unnaturally the inference has been made that forestry in itself is a thing for older and more densely populated countries, and that forest-management is inapplicable and incapable of adaptation to the conditions under which we live. It is true, on the contrary, that the treatment of German forests is distinguished above all things by an elastic adaptability to circumstances, which is totally at variance with the iron-clad formality which a superficial observation may believe it sees. It is equally true that its methods could not be transported unchanged into our forests without entailing discouragement and failure, just as our method of lumbering would be disastrous there; but the principles which underlie not only German, but all national forest-management, are true all the world over. It was in accordance with them that the forests of British India were taken in hand, and are now being successfully managed, but the methods into which the same principles have developed are as widely dissimilar as the countries in which they are being applied."

So forest-management in America must be worked out along lines which the conditions of our life will prescribe. It never can be a technical imitation of that of any other country, and a knowledge of forestry abroad will be useful and necessary rather as matter for comparison than as a guide to be blindly obeyed. It must be suited not only to the peculiarities of our national character, but also to the climate, soil and timber of each locality, to the facilities for transportation and relations of supply and demand, and the hundred other factors which go to make up the natural character of a hill-side, a county or a state. Its details cannot be laid down *ex cathedra*, but must spring from a thorough acquaintance with the theory of forestry, combined with exhaustive knowledge of local conditions. It will necessarily lose the formality and minuteness

which it has acquired in countries of older and denser settlement, and will take on the character of largeness and efficiency which has placed the methods of American lumbermen, in their own sphere, far beyond all competitors.

Correspondence.

Hardy Plants in Flower at Short Hills, New Jersey.

To the Editor of GARDEN AND FOREST:

Sir,—I went over to the United States Nursery a few days since to see, more especially, what effect the long spell of dry and insufferably hot weather prevailing lately had had on the hardy plants. This is a rather severe test, since the plants are fully exposed on a hillside which is somewhat dry, but I failed to notice any injury visible. This is probably because the plants are well cultivated, with the soil kept loose, a condition of things not always possible in a small garden. Lilies at this season, perhaps, call for the first notice. There was a fine selection of *Lilium auratum* varieties, *L. auratum macranthum* (or *platypetalum*) being the gem of the collection. This variety is very distinct, having broader leaves than the type. In well-established plants the stems are an inch or more in diameter. The flowers are very large, twelve inches in diameter, with pure yellow bands and studded with yellow spots. *L. auratum pictum* has bands shading from red at the tips of the petals through yellow to green at the centre. *L. auratum vittatum rubrum* has a dull crimson band, in some cases very broad. *L. auratum Witte* is a pure white variety, with a clear yellow band. The typical *Auratum* Lilies are such popular plants that these rarer varieties are well worth noting. Some double-flowered Tiger Lilies made a broad mass of color and individually were striking flowers. *Delphinium Sinense* was in broad masses in three colors, white, dark blue and light blue, the latter being especially pretty and showy. This is a rather low-growing variety some eighteen inches high at present.

Pardanthus Chinensis is a rare plant with reddish orange flowers spotted brown. It is iridaceous, with sword-like, stem-clasping leaves, and seems to be a distinct plant worth growing, though probably not reliably hardy further north. Midsummer, of course, brings many yellow Composites to perfection. Besides the ever-present *Anthemis tinctoria* I noted that Messrs. Pitcher & Manda grow *Rudbeckia speciosa* (*Newmanii*) in quantities. This is certainly a showy Cone-flower, very effective in masses. Another plant labeled *R. subtomentosa* was an interesting variety, with long, narrow petals and greenish yellow cones.

Heliopsis lævis is a native Sunflower, grown here largely, but it does not strike me as producing a desirable effect except for a wild plantation. Hardy Sunflowers are deservedly popular plants. Probably the best selection that can be made is *H. decapetalus*, *H. decapetalus multiflorus*, *H. rigidus*, *H. lætiflorus*, *H. orgyalis* and *H. Maximilianii*. The two latter have very distinct and attractive foliage at all seasons, the narrow drooping leaves proving peculiarly effective. To the above varieties might be added *H. mollis* for a bold group, a plant of very stiff erect habit with broad foliage and *Inula*-like flowers.

The photographer was busy over a new Sunflower of an undetermined species, which was a very striking plant about three feet high, entirely covered with deep yellow single flowers about two to two and a half inches in diameter, and individually very neat and distinct. The foliage was small, and though not abundant seemed hard and good.

Few flowers can vie in color with *Lobelia cardinalis*. A mass of Cardinal-flowers seemed as happy in this dry soil as in its native bogs. The hardy Blanket-flowers (*Gaillardia grandiflora*) are effective plants when well-grown, though they seem to decline to take the compact form of the catalogues. There are few hardy plants which have a longer season of flowering or are altogether more satisfactory. *Achillea*, The Pearl, has deservedly excited much attention lately, as it is a great improvement on the old Milfoil, *Ptarmica*, one of the weediest and most straggling of hardy flowers, though useful for its small white blossoms.

Elymus glaucus should interest every lover of grasses. It is very glaucous, and a good clump would excite attention in any garden. Another somewhat effective foliage-plant grown here is *Eryngium amethystinum*, one of the brightest of the Sea Hollies. I was glad to see a lot of *Viola tricolor*, the old-fashioned Heartease, or Johnny-jump-ups, of our grandmothers' gardens. Mr. Manda thinks he has a treasure in a new double purple *Datura*, which is certainly a vigorous

grower and bears a wonderful flower, quite as big as the *Brugmansia*.

In the houses I found a new *Begonia* species (tuberous), with the habit of *Martiani*, but with handsome spotted leaves and pinkish stems. Many varieties of Orchids were in flower, the most striking of which was a pure white form of *Cattleya Gaskelliana*. The great collection of *Cypripediums* here always gives me a sense of confusion, it is so impossible to comprehend the wonderful variety in the time at one's disposal. When Mr. Manda casually picks up a small pot graced with three or four leaves and remarks that it is the other half of a plant which he has sold for \$675, one muses on his fifty-cent specimens of the same genus at home and concludes that only the *Cypripedium* fancier can do justice to the subject.

Home-made Linen.

To the Editor of GARDEN AND FOREST:

Sir,—It is almost with a feeling of veneration that I now spread my home-spun table-cloths to serve for dinner. They are the last of a trunkful of linen brought over the Atlantic thirty years ago. Throughout this long period they have been in constant use, but now, unless supplemented by newer fabrics, their end is at hand. For more than fifty years the hands that so willingly spun and wove these threads for others' use have been resting in the grave—hence the sacredness which attaches to these relics of a former generation.

In the German household the love of linen is a passion. During the French wars under Napoleon when, from every town and hamlet, the terror-stricken people fled before the approaching armies, before all else they sought to save their many chests of home-spun linen, and when peace returned, what had escaped the Argus-eyed enemy was tenfold more precious, because of the horrors witnessed and the dreadful pangs endured. And even to-day the German woman prizes, far above rubies, her piles of snowy linen, the labor of many happy hours.

Here in this country the use and sale of imported linens assume yearly larger dimensions. The people are learning to realize its value and comfort as an article of wearing apparel. The southern product, the cheaper cotton, supplies the world's demand. Why may not the north add to its resources by reviving this old and important industry, and raise, at least, sufficient flax for home consumption? The women, too, would gain by its revival. Instead of spending time and strength upon the almost worthless trash called bric-a-brac, which cumber rather than adorns their homes, they might again possess their stores of home-made linen, which far surpasses in value and durability the best product of the machine. We live only for a day. Why may we not go more slowly and evolve a truer prosperity with its resulting tranquillity?

In European countries, when at certain seasons the traveler turns his eyes over the landscape, he sees dotted here and there fields of blossoming blue which ripple in the summer sunshine like the waves of the sea. They are acres of blossoming flax, sowed and cared for with surprising interest by the members of the household to which it belongs.

During a lifetime of observation one sees many changes in the customs and sentiments of people and nations. As in Bible days, there is a time for everything. The coming World's Fair will offer a grand opportunity to show what feminine hands abroad are doing in the seclusion of the home, from the Hungarian peasant woman's world-famed embroideries of home-spun linen to the lace-like products of the hand and loom of working and gentle woman. The number and variety of fabrics produced from this little slender-stemmed plant, in itself so insignificant, are so enormous that it may be well worth while to consider its re-introduction into our own country.

Hartford, Conn.

Wilhelmina Seliger.

Albinos among Orchids.

To the Editor of GARDEN AND FOREST:

Sir,—In your issues of March 23d and June 22d the occurrence of a white form of *Habenaria psychodes* is noted. Last July I collected not *H. psychodes*, but *H. fimbriata*, on an open hill-side bog near Tannersville, New York, where it grew in quantities, and with it a white form as beautiful, if not more so, than its rose-purple neighbors. The flowers were identical as far as I could see, though possibly very slightly smaller. This year, on July 23d, in crossing the same bog, I found the *Habe-*

naria in full bloom, the white-flowered form, as last year, neither quite as large nor quite as abundant as the purple ones. It is a very handsome species, growing here from one to two feet tall among the Reeds and Grasses, the spikes often ten inches long and nearly three inches thick.

Anna Murray Vail.

Local Plant Names in New Jersey.

To the Editor of GARDEN AND FOREST:

Sir,—As our boasted civilization progresses, and as railroads penetrate farther and farther into the wild and remote corners of our country, primitive conditions will be replaced by those more complicated, and differentiation and redifferentiation will follow closely this process of evolutionary growth. The forests will be destroyed for fuel and timber (to be renewed later at great expense), the streams of limpid water will be dammed for irrigation purposes, and the cleared and irrigated land will be cultivated. The customs of a simple and unsophisticated people will suffer by the same ruthless hand of progress.

I was very much impressed by this fact while traveling, some time since, through the sparsely settled portions of southern New Jersey. The farther I journeyed from the railroad and the deeper I penetrated into the lonely barrens and swamps, the more unsuspecting of strangers the people became, and the more hospitable. A man was harrowing a piece of sandy peat soil, near his one-storied cabin, with a triangular harrow, constructed of green limbs, into the framework of which, at irregular intervals, through auger-holes, were driven pointed sticks. An ox, attached to this primitive agricultural implement by means of a clothes-line spliced together and a bent stick as a yoke, was slowly breaking up the soil for a truck-patch; the poor beast was switching its tail in the vain endeavor to keep off the troublesome mosquitoes and the galling and persistent woodflies. This interesting picture of man, ox and harrow recalled the descriptions given of the early Aryan culture, when barley, wheat and flax were planted, and the ground was stirred by a crooked branch of a tree, tipped probably with the tine of a stag's antler, which served crudely as a plow.

Local names survive, as a general rule, in the process of speech evolution, and bear evidence of the cultural stage and inventive genius of a people in introducing new words for new phases of nature, and to describe new animals, plants and things. My purpose is to record in GARDEN AND FOREST a few of the local plant names current in parts of southern New Jersey. The fishermen along the Little Egg Harbor River call the Eel Grass (*Zostera marina*) Tiresome Weed, for, as they pull against the current in sailing to and from the ocean, the "grass wrack" entangles their oars and retards their movements. They also call the most beautiful of our spring Orchids, *Cypripedium acaule*, "Whip-poor-will Shoe," which is quite as poetical as *Lady's-slipper*.

The common Pitcher-plant, *Sarracenia purpurea* (*Side-saddle-flower*, *Huntsman's-cup* in *Gray's Manual*), is called locally in Cape May County "Dumb Watches." The beautiful purple flower grows from the centre of the rosette of pitched leaves below, and after a time the purple incurved petals fall, exposing the summit of the broad, expanded, petal-like stigma. The five green sepals remain, and resemble, in the imagination of the peninsular New Jerseymen, a watch-case, and the convex surface of the expanded stigma is likened by them to the face of a watch. This vegetable time-piece, with no hands to point the hours of the day, without the constant tick, tick, tick, is dumb. The whole plant is denominated, very significantly and ingeniously, "Dumb Watch," or simply "Watch."

A person interested in folk-lore might find an interesting field for investigation and research among the simple, hospitable and intelligent inhabitants of the shore and inland towns of the Pine-barren regions of southern New Jersey.

Philadelphia, Pa.

J. W. Harshberger.

Notes.

In vol. xvii. of the *Botanical Gazette* Mr. John M. Coulter recently published a sketch of the life and labors of the late Sereno Watson, with a portrait and a view of the interior of the herbarium of Harvard University.

The Rose, *Gustave Piganeau*, was sent out in 1889, but it takes some time for a new variety to be fully tested. This one is spoken of very highly by the English growers, and it has held a very prominent place at the exhibitions there this year. The flower is very large and yet it is good in form

and has a clear carmine-like color without any dingy suspicions of lilac or purple which mar so many Roses which are otherwise good.

The International Botanical Congress, to be held this autumn at Genoa, Italy, will open on the 4th of September and will close on the 11th, unless there seems good reason for prolonging it a little further.

Tomato-plants which have been growing over vigorously during the recent warm and moist weather may have failed to set much fruit. Where this is the case a sharp spade should be run down beside them to prune off the roots, and this will turn the vigor of the plant toward forming fruit.

The project of removing the Botanical Garden in Berlin to a new and more favorable locality has long been under discussion. Plans for carrying it into effect have now been decided upon, and Herr Perring, Royal Inspector of Gardens, has been commissioned to examine the other great botanical gardens of Europe in search of helpful information.

The manufacture of a new material called Bamboo-sheeting is said to be rapidly extending in the province of Wenchow, in China. The cane is split so as to form a sheet which is softened in boiling water and then pressed out flat. When dried, the sheets are ready for use and are employed for veneering as well as in making trays, fans, screens and open-work carved panels.

It takes many years, and often many generations, to develop a fruit or vegetable with the best edible qualities from its original wild state. It was the opinion of Dr. Gray that if modern civilization had begun in America our Ground Nut (*Apios tuberosa*) would have been the earliest developed esculent tuber, and would probably have held its place among the first, along with Potatoes and Sweet-potatoes.

An official reward for a new large-flowered Pelargonium, which is called Lisbeth Moncorps, and is the offspring of the varieties Mabel and Nympha, was recently bestowed in Germany upon Herr Moncorps. The plant is described as extremely sturdy and floriferous with flowers of a very pure color; and particular attention is called to the fact that, in ten months from the seed, Herr Moncorps had raised a specimen bearing about thirty strong flowering stems.

Late-blooming Tamarisks are just now very ornamental. Specimens that were cut back early in the spring are now waving their long and slender branches covered with fern-like foliage and pointed with great clusters of pink flowers. This is one of the shrubs which do very well where the sea winds prevail and even where the salt spray of the sea can reach them. But they do equally well farther inland, and are among the most beautiful trees which flower in late summer and early autumn.

We observe in some florists' windows a repetition of the practice which prevailed three or four years ago, of using the large white flower-heads of *Hydrangea paniculata grandiflora* on long stems, in large vases, with a few spikes of *Gladiolus* of some pronounced color. This makes an effective combination, as well as a very durable one, for the *Gladiolus* will continue to open its flowers in succession for a long time, and the *Hydrangea*-flowers will not only remain without wilting for a fortnight in a warm room, but will dry on the stem and preserve their creamy color throughout the winter.

Osbeck's variety of *Rhus semialata* is now ornamented with its large panicles of flowers, which are not a pure white, but which are nevertheless quite showy at this season, since they stand out well from the very dark green and clean foliage of the tree. None of the trees we have seen are more than twenty-five or thirty feet high, although, perhaps, they will attain considerably larger proportions in this climate. It is not as graceful as our native species, since the branches are not furnished with leaves except at the extremities, so that the tree has a rather bare and open look about the main branches.

In a pamphlet called *Chicago and the Columbian International Exhibition*, recently published in Berlin by the Imperial Commissioners for the Fair, German horticulturists are given all needful information and are heartily encouraged to make the best possible exhibition. We are glad also to find that *Gartenflora* calls attention to the fact, which we have already noted, that at a special meeting of the American Seedsmen's Association a cordial invitation was extended to European seedsmen, thus disposing of the unfortunate rumor that our

dealers had threatened to boycott such foreigners as might venture to compete with them at Chicago.

Phoenix Park, in Dublin, is more than six miles in circuit. It contains something like 1,700 acres, and consists of wooded slopes and deep valleys, with lakes in the hollows, and broad expanses of Furze-covered land and an abundance of majestic old Oaks, Elms and Beeches. Fifteen hundred sheep and a thousand fallow deer, said to be the finest in Her Majesty's dominions, are grazed in the park. The People's Garden is the name given to an area of about sixteen acres in the park devoted to the cultivation of various kinds of flowers. This flower-garden is very convenient of access, being within four hundred yards of Sackville Street, the principal street in Dublin.

Mr. Andrew D. Hopkins, of the West Virginia Experiment Station, writes to *Science* that one of the bark beetles (*Dendroctonus frontalis*) is destroying many coniferous trees in that section. It has generally been held that these insects do not attack living and healthful trees; but investigation shows that vigorous individuals of five species of Pine and of the Black Spruce have been killed primarily by the attacks of this beetle, which preys upon the green bark. Trees from five inches in diameter up to the largest specimens of White Pine have been ruined by them. When attacked in the autumn the trees may remain green until spring, when other bark and timber beetles re-enforce the original invaders to the number of twenty-five species. Later on these scolytids are followed by insects belonging to other families, until, in a dead or dying tree, there may be hundreds of species and millions of examples breeding in and feeding on every part of the tree, from the base to the terminal twigs, rendering it worthless for lumber within a year after it dies.

It is a pleasure to call the attention of instructors in botany to Professor Byron D. Halsted's brief article, "Beginnings in Botany," published in the August number of the *Popular Science Monthly*. "Much has been said," writes Professor Halsted, "largely in a theoretical way, concerning the general question of university extension. Various experiments have been made, and by another year definite plans will be matured for the popular presentation of many of the subjects that come within the scope of the extension movement as now understood by those who have had the most to do with the scheme for the education of the masses. The writer has recently finished a brief course in botany, and as the method pursued differed in some features from any previously followed, there may be sufficient reason for presenting an outline of the ground covered and of the ways and means employed for bringing the subject to the attention of a popular audience." Of course, it is impossible here to condense Professor Halsted's account of his work, but we feel sure that it will give helpful hints to all other persons similarly engaged.

The Michigan Flora, prepared for the thirtieth annual report of the Secretary of the State Board of Agriculture by Professors W. J. Beal and C. F. Wheeler, is much more than a simple catalogue of the plants of the state of Michigan arranged in the order of their botanical sequence. The pamphlet opens with a brief account of the topography of the state, dividing it into ten regions, whose physical characteristics are described, and whose outlines are laid down on a map. Rather full lists of the plants which are characteristic of each of these regions are then given. Notes on climate and distribution are added, and then come some interesting chapters on the trees and shrubs of Michigan as compared with those of the rest of the world, with the reasons why the Michigan flora is so rich and why there are so few species in Great Britain, for example. Interesting lists of trees, selected for various qualities, are furnished, as, for example, the native trees and shrubs which should be selected for the color of their leaves in autumn; small trees which are distinguished for their flowers; shrubs and trees which are distinguished for beautiful fruit, and those which are distinguished for showy or brilliant colored bark. Then come lists of plants which twine or climb in different ways; evergreens that turn to a bronze color in winter; plants suitable for winter bouquets; bog and marsh plants which are promising for cultivation, and native Ferns which deserve to be cultivated; trees which indicate a fertile soil, and others which indicate a barren soil; trees valuable for timber and for firewood; trees most durable as posts and sills, and most suitable for cabinet-work—all these and many more subjects are treated in an instructive and entertaining way in this pamphlet, which will be found interesting to very many persons outside of the state of Michigan.

A National Forest-policy.

IN the closing days of the last session of Congress, Senator Paddock's bill "to provide for the establishment, protection and administration of public forest-reservations and for other purposes" was reported favorably to the Senate, and although it was impossible at that late hour to secure any action upon it, the bill was placed on the calendar ready to be called up at the beginning of the next session. In the executive machinery authorized by this act there may be some details about which opinions will differ, but this could be said of any act devised for this purpose, for it is hardly possible that a complete and entirely satisfactory forest-policy could be inaugurated at once. A perfect policy can only be developed after years of careful experience; but, inasmuch as we have no policy whatever, what is now needed is a measure which will secure some comprehensive preliminary work with the broad outlines of a general system, and these requirements are fairly met by the present bill.

We have said that the country has no forest-policy, and we are reminded by the very interesting report which has been printed with the bill that the Government does not know with any accuracy how much forest-land still remains in the public domain, and it knows even less about the quality and quantity of the timber which is now standing on that land. The most accurate statement which can be made now is that the United States Government holds an area of something less than seventy million acres designated as woodland, and mostly situated on the slopes and crests of western mountain-ranges, and no more definite knowledge can be had without long and laborious investigation. This property of unknown extent and value is left without any proper administration, to be ravaged every year by fires and by illegal and wasteful cutting. Some special measures for managing these forests have been enacted, it is true, but they have proved rather detrimental than other-

wise, and it is confessed in a public document that the impossibility of securing, in a straightforward and honest way from the Government, either timber or timber-bearing lands, has compelled the citizens of nine states and territories to become criminals if they take the timber which is necessary to enable them to exist. It has been asserted that more timber has been burned in a single year than has been legitimately used since the settlement of the country, but even if this is an exaggeration it is true beyond question that we are squandering our inheritance at a ruinous rate, and that unless this reckless destruction is arrested we shall, in a short time, not only be without a sufficient amount of timber for the economical uses of the country, but we shall suffer a long series of ever-increasing disasters which, as experience has demonstrated over and over again, will certainly follow if the forest-cover is removed from the sources of our great rivers.

Now, whatever is true as to the influence of the forest-area upon climate and meteorological phenomena, it is agreed by all authorities that a forest-cover exerts a salutary influence upon the water drainage and soil conditions. The French Government has already spent \$35,000,000, and expects to spend still more than this amount in the future, to repair the damages done by deforesting the mountains of that country, and it certainly is the part of wisdom to be warned by such an example. Fortunately, a forest need not become unproductive because it is held permanently to preserve the conditions of soil and water, which make agriculture and even existence possible over large areas. Under proper management our present forest-resources can be maintained and even grow in productivity every year, but this is not possible so long as the forest is under private ownership. The fact that a crop of timber requires, at least, half a century for its development shows the necessity of stable ownership and a conservative system of management. A forest-policy worthy of the name must be organized and administered in the interest of coming generations, and the state, which never dies, can alone be trusted with interests in the distant future. Beyond all dispute, then, the forests on non-agricultural lands of the national domain should be held as the property of the whole people forever.

The new law provides, in the first place, for a survey, to determine the extent and location of all forest-lands, after which the President is to withdraw from sale and entry all such lands except those that are found to be more valuable for agriculture than for forest-reservation. These non-agricultural timber-lands are to be transferred from the Department of the Interior, where lands are held only for disposal, to the Department of Agriculture, which is designed to look after cultural matters, and where a bureau in charge of forestry-matters exists. To save expense at the beginning, and to create as quickly as possible an efficient protective service, the army may be employed for this duty, as it has already been used in the Yellowstone and California parks. There is no occasion here to explain the provisions for cutting timber under license, or for the creation of a force of officers to attend to the business of forest-administration proper. It is only necessary to add that the system proposes a separate and complete administration, to be carried on by competent men under expert advice, and the principle is steadily kept in view that while the service of protecting water-sheds is of sufficient national importance to warrant expenditure out of other funds, nevertheless this service should be made to pay for itself by the sale of surplus forest-material.

In short, the immediate effect of the bill will be to ascertain just how much timber-land the Government has and where it is situated, the withdrawal from sale by the General Government of all such land and its protection by the army until a complete and effective forest-service can be organized. It is to be hoped that the meetings of the various scientific associations during this summer and autumn, as well as the conventions representing the various branches of horticultural and agricultural effort, will bring

to bear their collective influence upon members of Congress and urge the passage of this bill. A bill which has advanced no further than a favorable report in one house of Congress has many risks to run before it can become an operative act. This is the first time, however, after years of petition and entreaty, that a bill so good as this has ever been placed on the calendar, and if every man and woman in the country who has this cause at heart would make a personal effort to convince his or her representative in Congress of the desirableness of the legislation proposed, there is little doubt but that the law could be enacted during the next session of Congress.

The Temperate House at Kew.

THE temperate house, or winter garden, at Kew is one of the largest and handsomest plant structures in Europe. It was built thirty years ago from designs by Decimus Barton, the architect of the Kew Palm-house. Only a portion of the original design has been carried out, but it is still hoped that the whole will be completed. When this is done the whole building will consist of a centre connected with two wings by two small octagons. The centre and octagons, which were erected thirty years ago, are devoted to the cultivation of Australian, south African, Mexican, south European and Asiatic plants which thrive in a temperature from which frost is excluded. The centre is 212 feet long by 137 feet in width, and it is sixty feet high. Except the plants on the shelves against the walls of the house, the whole of the collection is grown in long parallel beds three to four feet deep. The main features in the house are the Tree Ferns, Palms, Acacias, Sikkim Rhododendrons, Camellias, Araucarias, Dammaras, etc. Such plants as *Araucaria excelsa*, *A. Bidwillii*, *A. Brasiliensis*, *Dammara robusta*, *D. australis* and *D. Moorei*, *Cyathea medullaris*, *Seaforthia elegans*, *Chamærops Fortunei*, *C. humilis*, *C. Martiana*, *Camphora*, *Podocarpus elongata* and *P. Totara* are represented by exceptionally large specimens, some of which almost touch the roof. The central walk, of which a view is shown on page 401, is bordered with Tree Ferns, Bamboos, Palms, *Musa Basjoo* and similar plants of striking appearance. The charm of this house is in its comfortable temperature at all times of the year, the natural arrangement of the plants and their generally robust health. A catalogue of all the species grown in this one house would surprise many people by its length and comprehensiveness. A gallery surrounds the house inside, and from this may be obtained a good view of the grand Tree Ferns, Palms, etc., which can scarcely be seen from the ground.

London.

W.

Overland in the Cayuga Country.—I.

IT was a bright morning in July when I drove down the great University Hill, at Ithaca, for a trip over the plateau which lies between Lakes Cayuga and Seneca. Rain had fallen a day or two before, and all the hill-sides stood out in the glory of a bountiful harvest. The great West Hill, which rises 800 feet above the valley beyond Cornell University, presented a maze of patch-work blocks and colors. Far up toward its crest the continuous green marked the region of hay; farther down, the irregular blocks and colors indicated wheat and barley and oats, each spreading a different hue under the steaming morning sun, and still farther down were blocks of orchards, in which the rows of Apple and Pear trees looked like the Currant-bushes in my garden, while the lines of Grapes were only distinct enough to add a seamed appearance to the hill-side. This alternation of the farm-crops is not accidental to the great West Hill at Ithaca, for one sees it, or something like it, in all countries where small lakes and rivers lie among the hills. The fruits love the protection of the water, and the orchards and vineyards and berry-gardens may be seen everywhere among these inimitable New York lakes lying far down the slopes next the water's edge. Nor is this the only advantage which the fruits obtain by this proximity to the water; they are nearer the means of transportation, and their owners are thereby brought into more frequent and intimate contact with their fel-

lows. It is undeniable that the fruit-grower is usually a better "posted" man than the general farmer. His environment educates him. He must deal with his products quickly and systematically; he must know the markets, and he must contend with almost innumerable pests. The visits of the commission-house agents keep him in touch with the outside world, and the daily or weekly returns from his salesmen drill him in correspondence and business. The grain-farmer hauls his wheat to the elevator and receives his pay in cash, but the fruit-grower depends upon the mails for his returns, and in proportion as the farmer patronizes the post-office does his education grow. So the fruit-grower receives a telegram from his salesman, and takes it as a matter of course, but a telegram going to an ordinary farm-house is usually a signal for anxiety.

This hill rose in front of us, while to the north stretched the blue waters of the beautiful Cayuga. If the reader will consult an atlas of New York he will be reminded that several lakes lie nearly parallel with each other in the central western portion of the state. Of these lakes Cayuga is the largest, stretching out forty miles in length and in one place reaching a width of five miles. But, horticulturally, it is not the most important, for Seneca and Keuka strive for the honor of sheltering the most Grapes, Plums, Peaches, Apricots and Quinces. At the southern extremities of these three lakes the hills are high and steep; and the creeks have worn deep gulches in the soft slate. Some of these gorges are veritable cañons, like the Ithaca gorge at the head of Cayuga, whose walls rise bold and sheer to a height of over 200 feet, and often they are marvels of intricacy and beauty, like the world-famed Watkin's Glen at the head of Seneca. Toward the north the shores slope softly away into low and fertile plateaus. It is this table-land between Cayuga and Seneca lakes that we are to cross. We leave Ithaca at the head of Cayuga, and if we have no mishap shall reach Geneva, at the foot of Seneca. In the mean time we shall have passed over a country famous in the early days for its fertility, and shall reach the borders of one of the most remarkable horticultural regions upon the American continent.

For five or six miles we rise upon West Hill nearly parallel with the lake, and the deep blue waters, with the great university beyond, lie farther and farther below us, like a huge mirror reflecting the sky and hills. Meantime, we have passed through most of the horticultural region, which, at best, is small in the neighborhood of Ithaca, and it is mostly of a local interest. Yet there is no good reason, barring the indifference of the inhabitants, why this hill-side should not become as fruitful as similar slopes upon Seneca and Keuka lakes; and some day this must come to pass. Here are some old orchards, however, especially some dwarf Pear-orchards, which were planted under the inspiration of the Downings, and which, after the lapse of twenty and thirty years, are still thrifty and productive. But there is now abundant evidence that dwarf Pears are comparatively long-lived, although the notion to the contrary is everywhere present. The famous Yeomans Orchard, in Wayne County, is now nearly forty years old, and still in the full tide of its vigor. But dwarf Pears need better attention than most people give, and, therefore, few succeed well with them. I am convinced that one of the most important elements in the successful cultivation of them is to head them in annually at least half or two-thirds of the new growth. This process keeps the top low and greatly lessens the tendency to break from the Quince stock. About Ithaca this low heading is seen, trees which are thirty years old standing not over eight or ten feet high.

But the most significant features of the country we are now traveling are the signs of approaching age. Here is a Peach-orchard standing stark against the sky, every limb having died years ago from sheer old age; and there is a dwarf Pear-orchard, which was once the pride of the neighborhood, grown into a seared and mossy tangle, with here and there a Quince-bush to mark the spot where some pear has fallen. And this Pear-orchard is doubly sad, because we have but recently passed one as old which is in good health. The old Apple-orchards are a marvel. They are the relics of the early days, fifty and even seventy-five years ago, when the virile young farmers built the long walls and the wide-gabled houses. Now they are tall and gaunt, and their fruitage having failed through years of neglect, the owners have trimmed them up with axe and saw until their scarred and crooked trunks often rise ten or twelve feet high. They have long since outgrown their usefulness, and the best spray can scarcely penetrate their thick and lofty tops. Wise economy would have planted other trees long ago, and these would have been consigned to the kitchen-stove when old age first showed itself. But young orchards

are seldom seen, and the growers complain that apples no longer pay! Why is it that farmers can understand a Wheat-field, or a Potato-patch, but cannot learn the first lesson in tree-culture? Why is it that year after year they drag through the twelve months with no respite of shade or fruit and pass down to their successors only a bare and burdened farm?

Some of these old orchards bear profusely in occasional years, but the fruit is poor, being largely natural or seedling varieties, and the labor of picking from the tall and scattered trees is greater than the fruit is worth. I have a mind to stop at every farm-house and urge the people to cut down the old orchards; but no! that would be cruel. Better leave something to warm the hearts of the growing boys and girls and to give them some fragrant memories of the old farm, for I take it that most of them will leave it in due time.

But I am not saying that this is a poor or infertile country. I have only tried to say that there is little evidence of new purpose, for when the old trees pass away the orchards will be gone. We shall not travel far over these hills until we find evidences of the new life which freshens the soil and adds a new interest to the old farms. These farms which we are now passing, let it be said, grow as big crops of wheat and hay as they did in the early days, but the products must be wrung from the soil by greater effort. It is not true that the soil is exhausted in these lands which fifty years ago were the Wheat-fields of the west. Wheat-lands have given way to stock and the dairy in many cases, and yet Wheat is the staple, and finer crops of it never grew on the prairies of Illinois or Dakota than we are now passing along the road from Jacksonville to Trumansburg. We now lose sight of the lake except at intervals, and we find ourselves well up on the tops of the hills, ten miles from Ithaca. It is a beautiful country. The soft hills roll onward to the sky-line, ribbed by ravines and veined here and there by rectangular wood-lots, and everywhere strapped together by the winding roads. Broad quiet valleys run off here and there. The road-sides are freshly mown, for it is now haying-time, and their flowing outlines add the finish to pleasant country scenes.

The little hamlets along the way all bear the flavor of earlier days. The taverns at the four corners with porch touching the street, and the old open sheds and weather-beaten barns at the side, are reminders of the stage-days; and the village fathers still loaf about them with stories of their youth. Jacksonville is one of these hamlets, and it is particularly interesting to us, because the so-called original tree of the King of Tompkins County apple stands here. This is in Tompkins County, whence the apple got its name, and every gray-haired man will tell the story of the old tree. Nevertheless, none of them know its true history, and I, too, for obvious reasons, will not tell it. But the tree is grafted, and the grafts appear to have been brought from the lower Hudson River region early in the century. There the apple was known as the Flat Spitzenburgh, and its origin appears to be lost. Several persons brought grafts from this region to Tompkins County, but this tree at Jacksonville is the oldest one left, and it is the one from which most of the stock has been distributed. It is two feet in diameter and is still vigorous.

Cornell University.

L. H. Bailey.

In the Woods of Eastern Texas.

THIS part of Tyler County is a hundred miles from the Gulf of Mexico, and nearly as far from the west line of Louisiana—that is, it is about on the thirty-first parallel, and in longitude about $34^{\circ} 30'$. Geologically, this is in the older part of the newer Texas. With the exception of the large rivers that rise in the highlands northward and westward, the county is watered by numerous small spring-fed brooks, and sometimes small bogs occur. The soil is generally sandy and light, almost sterile in places. When mixed with alluvial deposits it becomes black and highly productive. It is well adapted to the cultivation of Pears, Peaches, Strawberries and garden-vegetables. Doubtless, in eastern Texas, as elsewhere, soils occupied by coniferous forests will become better after clearing by age and cultivation. Along the sandy banks of the little brooks the handsome little *Mayaca* is common. In some localities we see the tall yellow trumpets of *Sarracenia flava*, and in the small sphagnum-carpeted bogs *Utricularia cornuta* abounds with *Calopogon pulchellus*, *Pinguicula pumila*, a *Xyris*, and the queer, glistening red leaves of some Sundew not yet in blossom.

In the Pine-woods the pretty *Polygala polygama* is very common, and more rarely its more southern cousin, *P. lutea*.

Aristolochia reticulata is often seen, and very rarely in Texas, as my experience goes, is the northern *A. serpentaria* found among its neighbors. These species both have aromatic roots, and doubtless the same medicinal properties.

Of shrubs, *Stillingia ligustrina* and one species of *Myrica*, if not two, are everywhere. So *Itea* now displays its racemes of rather handsome but scentless white flowers. The Silver Bell (*Halesia*) and *Chionanthus* blossom much earlier. By the way, Snow-flower, as its generic name signifies, would be a more euphonious as well as a more significant common name than Old Man's Beard, or Fringe-tree, for the well-known last-named species.

But I set out to write of the Silva of eastern Texas. The sandy land is principally occupied by *Pinus mitis* and *P. tæda*. Pine-forests are pleasant, but weird places withal to visit. Their tall columnar trunks, needle-like leaves, the peculiar souging of the winds in their tops, such as is heard in no other forests, and their dislike for other forms of vegetable life, fill the visitor with an awe amounting almost to reverence. But one is glad to visit these primeval Pine-woods, because their existence in some forms runs back in time far beyond that of most of their deciduous neighbors, and yet one is saddened by the thought that the whole class of conifers are being destroyed by a short-sighted extravagance which, in a few years, will render a large Pine-tree as much of a rarity and curiosity as a *Sequoia* is now. Pine-trees here are not large, rarely becoming two feet in diameter, but they are tall, straight and handsome.

Here along the creek-bottoms are tracts of Beech-trees that would do credit to a New York forest. Beech is not only a stately tree, it is also a staid one. Though common in our original forests from New Brunswick to Wisconsin, and southward to central Florida, and in Texas to within reach of the salty breezes of the Gulf, yet the tree is everywhere itself.

We can count at least a half-dozen species of Oak, *Quercus aquatica* being the most abundant species; that species is set down in the books as a small tree. Near Nacogdoches, Texas, I measured one that was over twelve feet in circumference. At Arkadelphia, Arkansas, I met with individuals still larger and proportionally tall.

With the northern Hickories, Sugar Maple, Red Maple (small form), White Maple, White Ash, American and Slippery Elms, *Ostrya*, *Carpinus*, River Birch, Basswood, *Alnus serrulata*, Flowering Dogwood, Black Cherry, Witch-hazel, Box-elder, and the vicious *Rhus vernix*, which has not left its poisonous effluvium north, as a wrapped and swollen hand bears painful witness, growing everywhere around him, with sphagnum bogs and the Partridge-berry common in the Pine-woods, one would almost fancy that he was in a northern forest. But the strong, sweet odor of the Evergreen *Magnolia* mingled with its less pretentious but hardly less handsome and odorous deciduous congener, *M. glauca*, and the presence of Sweet Bay (*Persia*), Wild Peach (*Prunus*), of *Ulmus alata*, *Planera*, *Chinquapin*, Holly and Cassine recalls his wandering, and leaves him in the woods of eastern Texas. The Evergreen *Magnolia*, as it is usually seen in its native woods, is a very plain tree, with coarse, scattered branches, and bark becoming rough and scaling with age. In thinner woods and open fields it thickens up and becomes, at its best, the handsomest and most conspicuous forest-tree of its range. It sometimes attains a diameter of over four feet, and reaches a hundred feet in height. The species crosses the ninety-sixth meridian in Waller County, which is about its western limit. The most northern locality where I have seen the species growing in cultivation is Fayetteville, Arkansas, near the thirty-sixth parallel. *Magnolias* have lived there in apparent health for many years, though the mercury sometimes sinks to eight or ten degrees below zero. Holly grows in the gardens of Fayetteville with *Magnolia*, but not so vigorously.

Some botanical writers in describing *Ilex vomitoria* limit its range to a distance of twenty miles from the Gulf-coast. Nature is kinder and more liberal to the species, and allows it to grow in great abundance at least a hundred miles from the Gulf. So far as I can learn, no one is using an infusion of the leaves of Cassine as a substitute for tea. Some people did use them in that way during the privations of war, as they may have used seeds of *Sesbania Cavanillesii* as a substitute for coffee, and Mesquit-beans instead of wheat and corn for bread. But it is hardly fair to accuse southern people of committing such foolishness now.

Two weeks later than the date of the above notes, I saw in the San Jacinto valley, west of Conroe, nearly the same forest-growth. Sugar Maple, Beech, Witch-hazel and *Rhus vernix* had, however, been left behind.

Bastrop, Texas.

E. N. P.

Climbing Plants in the Pines.

WE have two distinct forms of *Ampelopsis* in the Pines. One has larger leaves than the other, of a lighter green, and the venation is much more marked in the larger form, while the flowers, which appear early in June, are about the color of Grape-blossoms. The smaller-leaved one begins to flower about the middle of July and continues in bloom until August. The buds and flowers are a dark purple color. It blossoms much more profusely than the other, is quite handsome, and attracts a great many insects, especially honey-bees. The leaves are very smooth, of a leathery texture, and dark bluish green in color. I found it in the Pines and transplanted it in my garden some five or six years ago, where it now covers a low-headed Apple-tree. I recently sent fresh specimens of both forms to Professor Sargent, who says of the late-flowering *Ampelopsis* "that it is certainly a curious-looking vine and ought to be transplanted to the Arboretum to see how it will behave there."

What a pity that *Rhus Toxicodendron* is poisonous. It is often confounded with *Ampelopsis* by those not versed in the scientific knowledge of plants. Others more observing, but not learned in botany, call both vines Ivy. *Ampelopsis* is the Five-leaved Ivy and not poisonous, while the other is called Three-leaved Ivy (Mercury), and known to be poisonous to many people. But how handsome it is in the Pines, clothing old decaying trees with thick overlapping foliage.

The wild Grape-vines, too, are handsome. One large vine often forms a sort of arbor by clambering over the tops of two or three small trees. Nothing can be more charming than these bowers often are; sometimes, however, the rampant vigor of the vine overburdens and oppresses the trees which support it in a way that excites our pity.

Very fragrant, too, with a spicy distinctness quite their own, are the blossoms of these wild Grapes. It has a genuine North American odor, and belongs as truly to this western world as does the breath of Indian Corn-tassels in an August evening. Compared with it the odor of garden Grape-flowers is tame and spiritless.

The Virgin's Bower (*Clematis Virginiana*), the most graceful of our wild vines, is now covering wayside shrubs with its snowy bloom, and its downy gray seed-clusters will be still more beautiful until late in autumn.

I occasionally see the Trumpet Creeper (*Tecoma radicans*) in damp places in the Pines and along country road-sides; but whether the winged seeds have been wafted from cultivated plants, or whether it is truly indigenous here as it is in Pennsylvania and in the southern states, I cannot tell. I only know that I never saw it in the early days of our settlement. But when planted it grows most luxuriantly and has to be kept in check, or it would soon swamp everything in its neighborhood.

The Bittersweet (*Celastrus scandens*) clammers about here and there in damp places, becoming very decorative in autumn, when its orange-colored pods open and show the bright scarlet seeds. The Trumpet Honeysuckle (*Lonicera sempervirens*) we also find, and it is almost evergreen with us. It is a handsome vine both in flower and fruit, and is quite extensively cultivated; but for the past few years it has been so badly infested with aphides that almost everybody has discarded it here. Strangely enough, I have never found the wild plants molested by these insects.

The Smilax must not be forgotten. Indeed, one who has attempted to penetrate our damp thickets will not be likely to forget it. *S. rotundifolia* and *S. tamnoides* are the most to be dreaded. The tangled masses, armed with stout prickles, climbing triumphantly over shrubs and trees, completely bar the way to many choice plants. And yet how handsome one of these plants can be made, especially *S. tamnoides*, with its bright shining evergreen leaves and clusters of black berries that remain all winter. And *S. Walteri* is also found here. This, too, has evergreen leaves, coral-red berries, and few or no prickles. It is a charming vine, and should be in cultivation.

Our Wild Yam is a graceful vine, neat and pretty, much more delicate than the Chinese Yam, which is sent out under the name of Cinnamon Vine. The Canadian Moonseed (*Menispermum Canadense*) is another delicate twiner, with pretty foliage and curious large stony seeds in the form of a crescent. *Apios tuberosa* is everywhere in the damp Pines, trailing over shrubs and bushes. In August and September it has thick, compact, dense racemes of brownish purple pea-shaped blossoms which are quite fragrant. But it spreads rapidly by underground stems, which are strung with roundish tubers, each tuber sending up twining stems.

We have one twiner in the Composite family—*Mikania*

scandens—which we find in damp places, climbing over bushes. It has heart-shaped leaves and panicles of pinkish colored flowers. It begins to bloom in July, and I have often found good clusters of flowers as late as October.

Some three or four species of the curious twining leafless Dodder are in the Pines. These plants start in life like all well-behaved vines, taking their nourishment, as in duty bound, from mother earth, but they soon become demoralized, yielding to temptation and let go their hold of earth and closely twine around their nearest neighbors, upon whom, like true parasites as they are, they henceforth wholly depend for nourishment and support.

Vineland, N. J.

Mary Treat.

New or Little-known Plants.

New Orchids.

CATTLEYA VICTORIA REGINA, O'Brien.—A handsome *Cattleya*, allied to *C. Leopoldii*, with large rosy purple flowers. The lip is three-lobed. It was imported by Messrs. F. Sander & Co., of St. Albans, and was awarded a first-class certificate by the Royal Horticultural Society on May 3d last. It is described in the *Gardeners' Chronicle* for May 7th, p. 568, and figured in the same work on June 25th, pp. 808, 809, figs. 115, 116.

ODONTOGLOSSUM ANDERSONIANUM PULCHERRIMUM, O'Brien.—A brightly colored form of the very variable series of natural hybrids between *O. crispum* and *O. gloriosum*, which are variously known in gardens under the names of *O. Andersonianum*, *O. Ruckerianum* and *O. hebraicum*. It may be briefly described as a darkly colored *O. Ruckerianum*. It flowered in the collection of R. B. White, Esq., of Arddarroch, Scotland.—*Gardeners' Chronicle*, May 7th, p. 586.

ODONTOGLOSSUM PLATYCHEILUM, Weathers.—A distinct and elegant species, with large, rather flat, white flowers, the lip being beautifully spotted with rosy purple. It flowered in the collection of R. I. Measures, Esq., of Camberwell, and received an award of merit from the Royal Horticultural Society on March 22d last. Strange to say, nothing is known of its origin, the only plant known having been acquired at the sale of the Downside collection.—*Gardeners' Chronicle*, May 7th, p. 587, fig. 84.

LÆLIO-CATTLEYA × *PHŒBE*, Hort.—A handsome hybrid raised from *Cattleya Mossiæ* crossed with the pollen of *Lælia cinnabarina*. The flowers are of a rich Indian yellow, with the middle lobe of the lip deep purplish crimson. It was exhibited by Norman C. Cookson, Esq., of Wylam-on-Tyne, at a meeting of the Royal Horticultural Society on May 3d last, and was awarded a first-class certificate.—*Gardeners' Chronicle*, May 7th, p. 598, also June 18th, p. 781, fig. 114.

LÆLIA × *LATONA*, Hort.—A handsome hybrid raised from *Lælia cinnabarina* crossed with the pollen of *L. purpurata*. It is like a small form of the latter, with deep yellow sepals and petals, and a dark crimson lip. It was exhibited at a meeting of the Royal Horticultural Society on May 3d last, and received a first-class certificate.—*Gardeners' Chronicle*, May 7th, p. 598, also June 18th, p. 791, fig. 114.

Kew.

R. A. Rolfe.

Foreign Correspondence.

London Letter.

ARISTOLOCHIA GIGAS, var. *STURTEVANTII*, is the great attraction at Kew this summer. It is grown in the Nymphæahouse, trained along the rafters so that the flowers hang over the water. What extraordinary flowers they are! There were five open one day this week, all very large and richly colored. Visitors are puzzled by them and are sometimes doubtful of their genuineness, as they are sometimes of the Cacti, which are supposed by some to be made of wood and cunningly painted. An artist friend said the *Aristolochia*-flower was a lady's calico sun-bonnet. We are very grateful to Mr. E. D. Sturtevant for this

Fig. 67.—Central Walk in the Temperate House at Kew.—See page 398.

plant, which is vastly superior to the type as named and figured by Lindley. Moreover, it is as easily cultivated as an *Allamanda*, and the disagreeable odor of its flowers is easily counteracted by having in the same house with it

such powerfully fragrant flowers as *Hedychiums*, *Stephanotes* or *Gardenias*. This plant has already been widely distributed from Kew. It is certainly one of the most interesting of all cultivated tropical plants. I might mention

that it is easily propagated from cuttings of the half-ripened shoots. Other large-flowered Aristolochias in flower now are *A. ornithocephalus*, *A. hians*, *A. tricaudatus*, *A. elegans* and *A. ridicula*. A collection of tropical species of this genus would be a most interesting feature in any large stove. Another large-flowered species, namely, *A. gigantea*, is now in cultivation, and will probably soon be available for collections generally. It has flowers nearly as large as those of *A. gigas*, *Sturtevantii*, but differs in habit, foliage and the absence of a tail.

LÆLIA MONOPHYLLA is a charming little species which was first introduced from Jamaica, where it is a native, to Kew in 1882, where it is now flowering freely. It is the smallest of all the Cattleyoid Orchids, the pseudo-bulbs being no thicker than a knitting-needle, three inches long, bearing a solitary leaf of the same length and a drooping one-flowered scape. The flower is one and a half inches across, not unlike that of *L. cinnabarina* in form, but more elegant, and colored rich orange-scarlet. A plant in a three-inch basket bearing five opened flowers is a picture. In Jamaica it is found at a high elevation, a fact which accounts for the preference the plant shows under cultivation for the conditions afforded in the cool Orchid-house along with the *Odontoglossums*, the temperature of the *Cattleya*-house being too high for it. It has been described under the name of *Trigonidium monophyllum*.

LILIUM LONGIFLORUM, var. *FORMOSANUM*.—This is one of the most beautiful of all Lilies. It may be described as *L. Harrisii* (the Bermuda Lily), with a narrow band of red-brown down the centre of each segment. It is very elegant, powerfully fragrant, and as easily cultivated as the Bermuda Lily. It is hardy in England, a good greenhouse plant, and at the same time, probably, is at least as suitable for tropical countries as any other Lily. For the trade growers of *L. Harrisii* it is probably a gold mine. I have lately seen a batch of about five hundred plants of it, which are the produce of the seeds of one plant ripened last autumn, and almost every one of these yearling seedlings is now producing a full-sized flower. The other forms of *L. longiflorum*, such as *Takesima*, *Brownii*, *Eximium* (*Harrisii*) and *Chloraster*, are all in flower now. There can be no longer any reason for keeping *L. Brownii* up as a species distinct from *L. longiflorum*. Among the plants of the variety *Chloraster* lately sent to Kew from Western China by Dr. Henry there are some very similar to *Brownii*, others approximating to *L. longiflorum*, and others suspiciously like *L. Wallichianum*. All the above-named are good garden Lilies, the most refractory being, perhaps, *L. Takesima* and *L. Brownii*, while *Eximium* and *Formosanum* are the best.

HYDRANGEA PANICULATA, var. *GRANDIFLORA*, and *CAMPANULA PYRAMIDALIS* well grown and in flower make, when arranged together, a most beautiful group in the conservatory. They are both hardy, of course, and both easy of culture, but, like many other plants of the same category, they pay for special treatment. The *Hydrangea* is greener and healthier in foliage, and larger and purer in flower when grown in pots and flowered under glass than it usually is when planted permanently in the open border. A group of these two plants in the Conservatory at Kew is greatly admired. The *Campanulas* are five feet high, and each plant has from three to five crowded spikes of rich blue flowers. The *Hydrangeas* are bushes a yard high, with from six to twelve grand trusses of pure white bloom.

BEDDING BEGONIAS.—The valuable qualities of the *Begonia* for summer-bedding have only recently been discovered. The tuberous kinds are now almost as prominent a feature in the flower-beds as the Scarlet *Geranium*, and, judging by the numerous new sports now on trial at Chiswick, their popularity is likely to increase. Among the latter I noted the following as distinct and useful: *Multi-flore l'Avenir* (Lemoine), plant only four inches high, with numerous spreading racemes of double crimson flowers; *Madame Louis Urban*, a deep pink-flowered variety, similar in habit to the preceding, and *Rosa multiflora*, a still

paler pink of the same character. Besides these there were six other kinds of very dwarf, small-leaved, free-flowering bedding *Begonias*, all from Monsieur Lemoine, of Nancy. *B. semperflorens rubrum*, *Vernon's* variety, and *Crimson Gem* are two names for a plant which is likely to become a favorite as much on account of the rich Beet-like purple assumed by its foliage when exposed to full sunshine as for its numerous rich crimson flowers. All the *Semperflorens Begonias* are good bedding plants, although only few people appear to be aware of that fact. One might ask what is there that would not thrive in the open air in summer if good weather could be assured. I have seen *Acalyphas*, *Cassias*, *Bouvardias*, *Zephyranthes*, *Hymenocallis*, *New Zealand Veronicas*, *Plumbago Capensis*, all used with good results as bedding plants. It is astonishing how we cling to pot-cultivation under glass for hosts of plants which would be infinitely happier away from both pots and glass. [Several of the plants named above are not rare as bedding plants in America.—Ed.]

The HERBACEOUS BORDER has become almost an established feature now in all good English gardens. It is the cheapest of all styles, and if only a little judgment be used in the selection of the various plants to be grown it is one of the most delightful. Until recently there was no really good herbaceous border at Kew, but one was made this year on one side of a range of houses. It had been a border of mixed shrubs, dull and monotonous as such borders generally are, good enough to screen a wall perhaps, but otherwise of no interest. The shrubs were grubbed out, save only a few evergreens, to provide for winter effect, and such flowering things as *Spiræas*; the border was widened, trenched and heavily manured. When finished it was twelve feet wide and a hundred and fifty yards long. It is at the present time a grand exhibition of *Dahlias*, *Hollyhocks*, *Sunflowers*, *Sweet-peas*, *Roses*, *Phloxes*, *Pentstemons*, *Stocks*, *Carnations*, *Pinks*, *Antirrhinums*, *Celsias*, *Foxgloves*, *Rudbeckias*, *Poppies*, *Pæonies*, and other plants. The lawn in front of the border is already worn brown by the visitors who crowd to inspect the flowers. The harvest of bloom began more than a month ago, and it will continue for two months longer. Perennials must, of course, be well represented, but it is astonishing how much of summer-flower glory and variety can be provided by annuals, the seeds of which are sown in spring and the plants never shifted.

London.

Cultural Department.

Notes on Shrubs.

AMERICAN amateur gardeners seem to be too ready to accept a popular idea that because Heaths and Heather do not naturally cover our waste grounds or moors, as in the Old Country, they cannot be made to thrive and bloom freely when introduced into the soil of the New World.

We rarely find a *Calluna* or *Erica* in an American garden, and yet if given proper conditions they will develop a very satisfactory growth, adapt themselves to their new surroundings, blossom freely in the month of August, when flowering shrubs are rare, and gladden the heart of every Scotchman or other enthusiastic lover of the Heaths of a former home.

Probably one reason for the prevalent idea that Heather cannot be successfully grown, when imported here, lies in the fact that there have been a great many small attempts to transplant them, almost every one of which has failed for some unknown reason. In too many cases full-grown plants have been dug up and brought over the ocean in pots, receiving treatment on the voyage which weakened them and prepared them for early decadence and death when planted in new and unfamiliar ground, and exposed to new climatic conditions. When growing from seed has been tried, the attempts have usually failed on account of a lack of knowledge of the proper planting of the seed and care of the young seedlings. It may, perhaps, be accepted as true that our climate is, as a rule, less favorable to their growth, because of the greater dryness of the air in summer, but there are many places along the sea-coast where the conditions do not seem very different from situations in which the Heather seems quite at home on the other side of the Atlantic.

The severity of our winters is no barrier, for we have the plants growing well without protection in Massachusetts, and it is recorded as growing without man's care on the coast of Maine, in Nova Scotia and Newfoundland. The patches of plants which have been found growing in these stations were once supposed to be indigenous, but, as Dr. Goodale has shown in his interesting article, published a couple of years ago in GARDEN AND FOREST (vol. iii., p. 62), there is reason to believe that all have started since the arrival of European immigrants and owe their existence to the intentional or accidental work of white settlers.

Many of the failures which have attended the attempted cultivation of Heather have undoubtedly been due to planting in unsuitable soil. The roots of plants of this family are generally exceedingly fine and delicate, and they require an open sandy or peaty soil with plenty of moisture; a heavy clay soil is fatal to them. Undoubtedly, the best method of introducing Heather is by means of seed. If one wishes to merely sow the seed broadcast and allow the plants to take care of themselves, a corner of a Cranberry-bog is probably the best place that could be selected, particularly if it is kept free for a time from rank-growing grasses and weeds. The seed may be simply scattered without any attempt at covering, as it is likely to fall into the little interstices in the ground, which will be filled by the first good rainfall. To grow the plants from seed artificially requires some attention and care, and should ordinarily be attempted only in a greenhouse or with the aid of a shaded and glass-covered frame or box. A good soil is composed of about equal parts of clean fine sand, peat and loam, and it should be well drained by having a thick layer of broken pots or brick beneath, with a layer of dead moss or sphagnum between the soil and drainage to prevent choking of the latter.

When the seed is sown it should have the slightest possible covering of fine soil evenly sifted over it, merely sufficient to cover it from sight. It may then be thoroughly watered with a very fine spray, and the surface of the soil should never be allowed to become dry at any time until after the seed has germinated and the little plants have formed good roots, after which they must not be allowed to suffer for want of moisture. It is sometimes a good plan to cover the beds with a layer of damp sphagnum until the seed begins to germinate, and when this period arrives the sphagnum must be removed at once. Shading the bed with a piece of matting placed a little above it answers about equally well for the shelter of the seed-bed and seedlings, and it is necessary to use the matting in shading the young seedling plants where the sphagnum has been earlier employed. After the seedlings are well up the glass may be raised or removed. When the plants are perhaps about an inch high, if growing thickly together, they should be carefully transplanted to fresh boxes or beds of prepared soil, giving them more room for growth; it is well to transplant two or three times before permanently planting out. If the plants are not kept in too active growth late in the summer, and have matured good woody stems, even though very small, they may be safely wintered in a frame by giving a covering of leaves or coarse hay; or if they have been grown in boxes in the greenhouse, they may be placed in a pit for the first winter, after which they may be planted out in prepared beds. If properly cared for, they should form good strong plants in two or three years, ready to begin blossoming and to be planted out where they are to remain permanently.

In a very large proportion of our country the soil is of a limestone or clayey character, where Heaths would be sure to fail unless a bed was specially prepared for them. It should be dug out for from two to three feet in depth and filled in with about equal parts of peat and clean fine sand. Soft or rain water should be used as much as possible when watering; hard water would probably be disastrous to the plants.

Where plants are already available, they may be multiplied with less trouble and more expeditiously by cuttings of the tender tips of the shoots taken at this season, and planted in pots or boxes of sand, or sand and peat, provided with good drainage, kept under glass and reasonably moist. The cuttings may be about an inch long or a little more; they should have the lower leaves removed, and should form good roots before winter. Where only a few plants are wanted from a parent plant they may very easily be obtained by layering. Propagation by cuttings or layers is absolutely necessary in increasing any peculiar form of a species, the Heather (*Calluna vulgaris*) having furnished several which are perpetuated by European cultivators. Among these there are forms with darker-colored flowers than the type, others with white flowers, while a very pretty form has double blossoms. Then there are forms which have been selected on account of their habit of growth, some being prostrate, others more erect and taller than the average,

while such forms as have been named *Pygmæa*, *Foxii* and *Densa* grow in pretty, compact, very dwarf tufts, but produce few flowers. This species of Heath is probably the hardiest and best for northern amateurs to experiment with in this country. After success has been attained in the cultivation of the more vigorous *Calluna*, other less vigorous and seemingly less hardy species of *Erica* may be taken in hand with every chance of some satisfactory result and pleasure.

Arnold Arboretum.

J. G. Jack.

The Wild Garden in August.—I.

THE wild garden is always interesting; it is nearly always beautiful, and its appearance undergoes a complete change every month of spring, summer and autumn. There is a great wealth of yellow flowers at this season, a predominance due to the large number of *Compositæ* in bloom. Several species of the Rosin Weed (*Silphium*) make a good display, but, as these are coarse-growing plants, they are out of place in any but large gardens. *S. perfoliatum*, the Cup Plant, is conspicuous on account of its ten feet of stem and bold ovate leaves. It is massive and striking in strong clumps, the yellow flowers, three inches in diameter, being borne freely at the top of the mass of luxuriant foliage. *S. trifoliatum* is not so tall by four feet, and its lanceolate leaves are smaller; but its similar flowers are produced in even greater profusion. The Compass Plant (*S. laciniatum*) is about five feet high, with flowers of a clearer yellow color than any of the others, and four inches across. The lacinate, hoary leaves, on long petioles, are from one to two feet in length, and they give the plant a quite distinct aspect. Some other interesting kinds will not bloom until a few weeks later, and thus their flowering period is prolonged. Large groups of these plants look well on the lawn, and they are admirable when associated with tall shrubs. They like a deep soil, and suffer but little from drought.

Heliopsis lævis, the Ox-eye, is very floriferous and showy, and a good plant for the herbaceous border. The stems attain a height of about four feet, forming a compact, shapely cluster when tied to a stake some inches shorter. The opposite leaves are ovate-lanceolate, of pale green color, and the rich yellow flowers, measuring three inches across, are excellent for cutting. The plant requires no special culture, and thrives well in any soil save that which is excessively light. *Lepachys pinnata* is similarly attractive and useful. It is hardly so robust as the *Heliopsis*, but more graceful. The elegant leaves are pinnate, and the drooping, pale yellow ray florets, with the conspicuous black sphere which constitutes the disk, give the flowers an agreeable charm. A large mass of this species is now a pleasing feature of the wild garden, the plants having been allowed to develop in their own way.

It would be difficult to pass the *Rudbeckias* without saying something in their favor, more especially as one of the species, *R. speciosa*, the gem of the genus, holds a foremost place among our herbaceous plants. It is from two and a half to three feet high, and absolutely covered with flowers three inches across, the outer florets deep yellow, and the large cushion-like disk dark purple. The leaves are ovate or lanceolate, but now hidden to a great extent beneath the close covering of golden flowers. *R. maxima* is a decidedly different plant, the stems of which are about five feet high, clothed with oval glaucous leaves (petiolate at the base and clasping above), and bear solitary flowers at the extremity. The cone-shaped, deep purple disk is fully two and a half inches high, the drooping ray florets two inches long, very broad, and of a clear yellow shade. This species is not at all common in gardens, and it well deserves more attention. It is singularly handsome when grown in quantity, and as a border-plant its merit is undeniable. *R. laciniata* is also desirable, being a free grower of stately habit, and producing its bright yellow flowers in great abundance. The *Rudbeckias* thrive well in ordinary garden soil, but they are partial to a position which allows them plenty of light.

An imposing mass of green and white is afforded by *Parthenium integrifolium*. The leaves are quite large, furnishing the stems to the base of the great flattened clusters of white blossoms, which, individually, are rather insignificant, but very effective in the mass. The plant is about four feet high, and grows luxuriantly in heavy soil. There are only a few straggling flowers remaining on *Asclepias tuberosa* to remind us of its brilliance in July. It was then one great mound of fiery orange-red blossoms, now replaced by pods which will, later on, give a good supply of seeds—the principal means of effective multiplication. It is a grand plant for dry, hilly situations, and so is *Opuntia Rafinesquii*, the best of the few Cacti which are hardy in this latitude. This Prickly Pear is ex-

tremely floriferous, the blooms being of a yellow hue with reddish centre.

But a small number of the Asters have as yet shown their blossoms. *A. macrophyllus*, a species with very large cordate leaves, about two feet high, was the first to flower. Its rays are of a whitish or lilac tinge, and the flowers are now at their best. It was closely followed by *A. corymbosus*, a similar plant with smaller ovate leaves and white flowers. *A. Herveyi* and *A. ptarmicoides* will soon be in full bloom. The ray florets of the former are violet, and those of the latter, which is an exceedingly graceful plant, pure white. The large pale blue flowers of *A. Lindleyanus* are just beginning to expand, as are the rosy purple blossoms of *A. Novæ-Angliæ*, one of the most beautiful species in the entire genus.

Solidago arguta is the only one of the Golden-rods whose full complement of flowers has appeared so far. It is a very pleasing plant, about three feet high, and most desirable on account of its early flowering. The flowers are of a lively yellow, leaves bright green, and the habit compact.

M. Barker.

The Water-garden.

AQUATICS are still the centre of attraction with their ever-renewed flowers, variety of color and the general animation which is never so marked in formal flower-beds. The Lotus (*Nelumbium speciosum*) always commands the first attention, as its noble flowers in the morning sun tower above its foliage, which is quite as noble, while the modest night-blooming *Nymphæas* hide their faces until the brilliant light is past. No aquatic has been more satisfactory this season than the Lotus, and none has required so little attention. Medium-sized roots have made rapid growth and flowered profusely, and are now established; but it is a question whether it would not be better, where cold winters render them uncertainly hardy, to make shallow tanks, eighteen inches to two feet deep, and plant every season. And yet the Lotus seems difficult to start in some places, and I have had the same trouble here when I buy dormant roots. I find no trouble when planting them in shallow water, and filling up as growth advances. For deeper water, plants with stronger growths and numerous roots can be used with safety. In all cases the water requires to get naturally warm to start active growth. The season was somewhat backward for planting, and it was the latter part of April before the roots above mentioned were planted, but they were flowering well the latter part of July, and will continue for some time. With few exceptions, the flowers are as large as those planted the previous year.

It is particularly necessary to have the tanks and ponds well stocked with fish. In tanks where I had few fish I had an abundance of Dragon-fly larvæ, which punctured the young growth and flower-buds of *Nymphæas*, and, of course, deformed them seriously when they were open.

One of the most ornamental of the Arrowheads is the double form of *Sagittaria Japonica*, which is now in flower. It will succeed admirably in a tub that is water-tight, or it may be planted in moist places or on the edge of the Lily-pond. The flowers are pure white, perfectly double, as large as a Carnation, and produced abundantly on a scape similar to that of our native species.

Dongan Hills, N. Y.

Wm. Tricker.

Francoa ramosa.—The *Francoas* are natives of Chili and belong to the Saxifrage family. There are but three species, and all are perennial but not hardy here, though they might be successfully cultivated in the more favored sections of the eastern states as they are in some parts of England and Ireland, where they are grown as border-perennials. These introductory remarks are necessary, as I know of no firm in this country that offer either seeds or plants of any of the species. Our seeds were obtained from Mr. W. Thompson, Ipswich, England. The popular name given to the plant in question is Bridal-wreath, owing to the long-branching sprays studded with pure white flowers, and it is surprising that florists have not taken the plant in hand, for it would be invaluable for summer cutting, either for indoor use in vases or for any other purpose for which cut flowers are desired.

Francoas are best grown from seeds which germinate readily, and the plants may be potted off separately and grown on to seven or eight inch pots, as they may require. The treatment given *Calceolarias* and *Cinerarias* would suit them well for the winter months. During the following summer the plants will bloom freely, producing as many as twelve sprays to a plant in a vigorous specimen, each spray being about

three feet long and flowering for two-thirds of the length. For grouping among other plants, either in the open ground or in the conservatory, nothing can be more admirable than *Francoa ramosa*, the flowers of which are pure white. *F. appendiculata* is another species with flowers that have a tinge of red with the white. The sprays are not so erect as in *F. ramosa*, but spread more freely and produce a very pretty effect when blended with other plants.

The only other species is *F. sonchifolia*, with which I am not acquainted, but it is said to be equally good, resembling *F. appendiculata* in the color of the flowers.

The season of flowering has lasted over two months with us, and this is a good time to make cuttings of the offsets from the old plant, many of which can be procured with roots. They may be treated as young seedling plants in every particular, and should flower next summer. Seeds are also produced freely here and may be sown as soon as gathered. As they are small, they may be treated in the same way as the seeds of the *Calceolaria*.

Melianthus major.—I see Mr. Gerard notes the beauty of *Melianthus major* as an ornamental foliage-plant. Too much cannot be said in its favor for this purpose. A word should be added as to the way to obtain or propagate the *Melianthus*. Only those who have tried cuttings know how difficult they are to root. It is rare, indeed, for any one to succeed in raising them in this way. I find that the seeds germinate as readily as those of the Castor-oil-plant, and make fine young bushy plants for use the same season. Our seeds were procured from the same source as the *Francoas*, and produced a nice batch of plants, one of which was left out last winter in a *Rhododendron*-bed and carefully protected with leaves, but it died.

In Ireland the *Melianthus* is perfectly hardy, and it probably would be equally so in many parts of the United States. It would pay some one in the south to cultivate the plant for the production of seeds, as with the *Grevillea robusta*. There would be a ready sale for the seeds when the plant became better known for use among summer decorative planting. Old roots lived over with us in the cold frame last winter after being lifted and cut back, and are now in the open border. With regard to *Grevillea robusta* a reliable English firm states that "seedlings are easily raised by those who can exercise patience, but we do not know any seed—not even the *Auricula*—which is so long and so capricious in germinating." They probably have to depend on seed from New South Wales, while seeds obtained here from trees growing in Florida germinate as freely as Radishes. Seeds that are imported from the antipodes are difficult to manage, and rarely germinate well, if at all. We have tried many kinds, but with indifferent success.

South Lancaster, Mass.

E. O. Orpel.

Tradescantia Warscewicziana.—The larger number of the greenhouse species of Spiderworts are cultivated for their ornamental foliage, but the species under notice not only deserves to be cultivated for its foliage, but also for its beautiful flowers. The plant in flower here is only a small one with a single stem, and was obtained from the Botanic Garden, Edinburgh, about twelve months ago. When the plant gets older it forms a branched sub-arborescent, stout stem, with recurved leaves, having a good deal the appearance of an Aloe. The leaves are about eight inches long, narrow-oblong, acuminate and sessile. The flowers are of a bright purplish rose color, and are produced on a densely crowded branched panicle. Although the flowers are small they are very effective, owing to their density, and as they do not all open at the same time, but in constant succession, the blooming season is of long duration. The cultivation of this plant is very simple; it will grow in any rich, open soil, but needs plenty of water at the roots. This is really a good greenhouse plant, and deserves a place in every collection, especially when it is old enough to form a branched stem. It can be increased from cuttings.

Costus igneus.—Although this plant was introduced from Bahia in 1882, it has not become common, and is very little known in gardens in this country. There is no reason why this *Costus* should not become a popular plant, as its cultural requirements are very simple. If potted in ordinary compost and given the same treatment as the general run of stove-plants it will both grow and flower freely. At this season of the year the bright orange-red flowers, which are different from any other of its associates, stand out conspicuously among stove-flowering plants. The roots of this plant are thick and fleshy, and they form a strong crown from which the stout, erect stems are pushed up to a height of from

eighteen inches to two feet, and are terminated by the head of blossoms. In the cone-like head of blossoms the flowers do not all open together, so that the flowering season is prolonged. The individual flowers are one and a half inches in diameter, and in color bright orange-red, two or three flowers are open together on the same stem, so that when a large plant is obtained they present a showy appearance. Like most of the other members of this genus, this species has also beautiful foliage, which is of a bright green color. It can be easily increased in spring by dividing the roots.

Correspondence.

Some Questions About Taste.

To the Editor of GARDEN AND FOREST:

Sir,—I have read with care your editorial on the subject of "Taste Indoors and Out," and beg to ask a few questions on a subject so fraught with interest to all who seek to beautify their places in the right spirit.

To begin with: How are we to know what is right and what is wrong? We do not all have a landscape-architect at hand to consult, and he is at best an expensive luxury, then what is to be the criterion of excellence? Taste is so much a matter of individual judgment that one person likes what another hates, and we are very unwilling to take another's ideas, unless we are quite convinced that he is an authority. You are right in saying that it is a good thing for women to interest themselves in this subject; but how are we to know what is un-beautiful from the highest standpoint? Our views about what constitutes an attractive drawing-room arrangement differ very widely, and there we are in a sense at home, but one woman likes ornament and succeeds in it; another disdains it, and produces a dignified and interesting effect without it; and it is more or less the same in our grounds.

Now, can you not tell us what to avoid and what to aim for in our gardens and places, and by what means we can attune our minds to such manliness of conception as shall produce a good result even on an estate? Are we women to be confined to the petty and the pretty forever, or may we not aspire to the loftier walks of landscape-gardening, even as some of us venture to try issue with senior wranglers in the higher mathematics?

Admitted that women are deficient in creative ability, where is the school in which we can learn at least the rudiments of an art so important as the proper planting of our grounds? Why can there not be schools of landscape-art as well as schools of architecture for our enlightenment where we can investigate the proper composition of a rockery or the exact formula for planting a bosquet?

If there is a rugged old tree in the neighborhood of my house, how am I to know whether its picturesqueness is in tune or out of key with its surroundings? At just what distance from the house should the natural give way to the formal? If I like a group of boulders on the edge of my terrace instead of a formal wall, how am I to be sure that my taste is faulty, and the authority who prescribes masonry instead of the boulders to be accepted unhesitatingly?

I think the trouble is that there is no law, and hitherto no inspired councils. The fact is, the fathers of landscape-gardening ought to hold such a council and give us the canon, and let it be infallible. I am not of those irreverent doubters who declare that the wisdom of men in council is no greater than the wisdom of each one taken separately; I am prepared to accept the faith devoutly, if only our Vatican will speak and let us know what is true orthodoxy. The trouble is, we are kept running after the Lo, heres! and the Lo, theres! and a dissenter's views are pronounced with as much confidence as those of the regular doctors, so that really we can't help getting "balled up," as the Andover men did about sheol at the time of the great discussion.

What is taste is really almost as hard a question to answer as what is truth, and if we once get on the wrong track there seems to be no reason why we should ever be led into the right one except by some happy accident.

How are we to distinguish taste from fashion, ephemeral beauty from that which is lasting? What is the test to apply to arrangements of trees and shrubbery, in which there is admittedly great variety permissible? There must be something, as there is in art, which makes things good or bad, excellent or violent, apart from individual fancy or the passing mode, and it seems desirable to find out what is the standard to which the wise and willing may repair with complicated

problems in composition, and have their doubts solved, and their taste uplifted on the spot.

Mr. Ruskin says that a person may not consider himself a critic in art until he can go at full speed through a gallery and know without stopping which pictures in it are important. I suppose, really, the truly cultivated landscape-architect can go galloping through a country-seat and know that it is dreadful without even looking at it, but minor mortals have to take their Louvres and Luxembourgs moderately and think twice before they know an early Raphael from a Perugino, and it is the same in a garden. I know people who actually like Horse-chestnuts and Purple Beeches, and are capable of planting groups of incongruous trees, and sticking to it that they look well together. How are such to be confounded and reduced to a proper state of mental receptiveness so that they will become capable of taking in new ideas? We all feel that GARDEN AND FOREST is doing a great work in that direction, but the more active our minds become the more we are disposed to question our teachers, and ask chapter and verse for the faith that is in them.

Nor do we do this in any carping spirit, but rather that we may ourselves lay hold on truth, not tentatively but with precision, growing in security and knowledge. Probably, if the landscape-gardeners could put their theories into words they would not do it, for it might spoil the business, but it would be interesting if we could get them to tell us what guides them in their decisions, and what we ought not to do.

Most people do not have time to do the requisite thinking to plan their places successfully, and therefore they relegate to a professional what might be an expression of their own individuality if they would put themselves into it with zeal. There is also the difficulty that trees are unhandy things for an amateur to experiment with, and one feels timid about dealing with them in any unconventional way, and so hesitates to make any very unusual disposition of them; neither can they be whisked about for nothing, but require men and money to deal with them successfully. Shrubs are somewhat easier, and what you aim at is more promptly attained; but even in the flower-garden we fail to see much that shows individuality of treatment, or even novelty of effect.

If this is to be a business for women, we really ought to begin at the beginning and understand how to go to work, and the editor of this paper is just the person to give us a few elementary lessons in the profession we are so eager to practice, and apparently in his eyes so little qualified to adorn.

I suppose the true way would be for us to begin with the flower-garden as a sort of primary school, and when we show some real aptitude in that we might be promoted to the intermediate department of shrubs, while only those who were graduates from both these schools would be entitled to go up higher and deal with trees in their proper relations to each other.

As to lessons in taste, those would have to be extras. I doubt if this country is far enough advanced to make a school of taste possible, and yet I am not sure but that it would be as much to the purpose as a school of philosophy. In our modern Athens, a peripatetic professor, illustrating his lectures by walks through the Public Garden and the Back Bay Fens, with occasional excursions to outlying parks, that might serve as a warning or example at will, would be deservedly popular, and we feel that we at least have the men competent to enlighten us if only they had the will.

Hingham, Mass.

M. C. Robbins.

Plant-labels.

To the Editor of GARDEN AND FOREST:

Sir,—Some years ago I wrote to you for advice on the subject of plant-labels, and received a very courteous reply through the columns of your valuable journal. The subject of labels is such an annoying one to the amateur, and seems still to be so far from a satisfactory solution, that I venture to add a suggestion. I enclose a label that has stood for over two years in a most exposed situation, where it was subjected to the full rays of the sun as well as to the rain and cold. It appears to be as legible as when first inscribed; and the black writing on the polished white surface renders it most easy to decipher. The label was bought in Paris, and costs seven francs a hundred at retail. It is of ordinary celluloid and could, I presume, be made more cheaply in the United States. The ink is a patented article, and costs 1³⁵/₁₀₀ francs per bottle at retail. The completed label would thus cost about a cent and a half. I have not yet found any other label combining to so great a degree the elements of legibility, durability and cheapness. I may add that I have seen these labels used for years in dark and damp wine-vaults without any apparent deterioration in legibility.

I must ask you to return the label, as it is the only one I have, and I desire to use it as a sample in sending for others.

Oakdale, L. I.

C. B. W.

[The legend on this neat label is perfectly clear, and the ink does not seem to have faded or "run" a particle.—Ed.]

Meetings of Societies.

The Florists at Washington.

THE annual meeting of the Society of American Florists at the national capital last week was more numerously attended than any which preceded it. The report of Secretary Stewart showed that the membership of the society had increased during the year and its influence extended in every direction. Mr. William R. Smith, Superintendent of the Botanic Garden in Washington, was elected President for the ensuing year, and Professor Trelease, of St. Louis, was made Vice-President, and St. Louis was chosen as the place of meeting for next year. Mr. John Thorpe, the Chief of Floriculture of the Columbian Fair, announced that all the floor-space of the great Horticultural Building had been already taken up, and that exhibitors from abroad had shown a greater interest than the florists at home, and had already applied for more than half of the space to be disposed of. The trade exhibit was particularly good, and filled the large lower hall of the Armory where the convention was held. Excellent displays of Orchids and other choice plants were made by Messrs. Pitcher & Manda, of Short Hills, New Jersey, and by Mr. H. A. Dreer, of Philadelphia. The display of Tuberous Begonias by Mr. J. W. Elliot, of Pittsburg, was noteworthy, and so was a collection of Cacti by a southern firm.

We give below condensations of a few of the more important papers read, and will give others in a future number of the paper:

THE PRESIDENT'S ADDRESS.

The address of President Dean was a careful review of the year in its business and cultural aspect. He noted in particular, not only a growing volume of trade, but a demand for a better quality of plants required for bedding, such as Crotons, French Cannas, Tuberous Begonias and aquatic plants. Among the improvements of the year were noticed the adoption of regulations for governing trade exhibits held at the time of the annual meetings. These rules will help managers to classify the exhibits, will facilitate the work of the judges, and enable exhibitors to display their certificates on the evening of the first day. The offering of gold, silver and bronze medals for new hybrids or seedlings, or for the discovery or introduction of new seedlings, will, no doubt, prove an encouragement to floriculturists in the fascinating work of cross-breeding and obtaining new and improved forms. The great improvements made in the Chrysanthemum, the Rose, the Carnation and other flowers is attributable to the high standard adopted at floricultural exhibitions, and the formation of societies for the purpose of improving special plants, like the Rose Society, the Orchid Society and others, was to be commended, since they would prove helpful auxiliaries to the parent society, and it was recommended that at the annual meetings, experts in each specialty should review their work and record the latest developments in their particular fields as a part of the proceedings of the society.

After speaking of the colossal proportions which the business of commercial floriculture had assumed in America, President Dean recommended the establishment of an institution which would afford scientific training and general business education for young florists. Floriculture is a profession which, above most others, requires special training, and the time has come when young men should know more than the mere routine practice of the trade, and should be instructed in the scientific possibilities of plant cultivation. He further recommended the establishment of an experiment station to which florists could refer the vexed questions which constantly arise in their practice. It might be practicable, and, indeed, advantageous, to unite these two institutions so that the students and professors of the college would form together the working corps of the station. No better material could be provided for the laboratory research of the student than that which could be supplied by inquisitive and eager florists throughout the

country. An institution like this would become the organized centre of investigation and training, and it would give an impetus to the work of discovery and the dissemination of knowledge of plant life, and would help to establish floriculture in its true basis as a science as well as a business.

In speaking of the approaching World's Fair, President Dean said that the Horticultural Building, now ready for the reception of plants, is the largest one ever erected, and that it behooved the society to see that every aid was extended to Mr. Thorpe so that the exhibit can be made worthy of the occasion and of the country. The main difficulty to be faced is that of obtaining and transporting plants of sufficient size to show well in such an immense building. State and local societies were therefore strongly urged to induce public-spirited citizens who owned desirable plants either to loan or give them to the department.

FUNGOUS AND OTHER ROSE TROUBLES.

Professor Halsted, in treating of this subject, said that the various species and varieties of the Rose have their full share of fungous diseases, no less than 165 kinds which prey upon the genus being recorded in the books. The black spot is a very wide-spread disease of the Rose, first described in 1826, now known in many countries and much dreaded. The foliage when attacked soon develops black spots, and the leaves becoming elsewhere pale shortly fall to the ground. As a result, Rose-houses badly infested show few leaves and fewer blooms. The microscopic structure of this fungus has been fully considered in the first annual report by Professor Scribner, of the United States Department of Agriculture, for 1887. Experiments have been carried on by the New Jersey Station to warrant the assertion that it can be controlled by the carbonate of copper compound, using three ounces of carbonate of copper, one quart of ammonia and fifty gallons of water. The spraying should be done once a week, using a hose and a nozzle that gives a fine spray. The point should be to wet every part of the plant, and yet not drench it. If many leaves have fallen from the plants they should be gathered up and burned. As with many other diseases, some varieties are more liable to the black spot than others. Within the past week the black spot has been observed by Professor Halsted upon a species of wild Rose (*Rosa humilis*).

Powdery mildew of Rose (*Sphaerotheca panosa*) is one of the oldest troubles of the Rose. This develops very suddenly on the foliage in the greenhouse or outside of it, giving the leaves a powdery appearance and causing them to become more or less misshapen. In a mild form the foliage may be only mealy, but frequently the surfaces become uneven and the whole leaf twisted. A remedy has been found and long applied in the shape of sulphur in one form or another. Professor Maynard, of the Massachusetts Experiment Station, finds a small kerosene-stove the most convenient for this purpose, and the sulphur, by means of it, is boiled in a kettle for two or three hours twice a week, the house being closed during the operation. The only precaution is to use no more heat than is sufficient to boil the sulphur, for should it catch fire it might damage the plants. In the *American Florist*, for July 7th, Mr. John N. May writes that the best way to get rid of the mildew is to close the house about eight o'clock in the morning, run the temperature up to seventy-five, then with a bellows fill the house full of sulphur, let it remain closed until the temperature reaches eighty-five to ninety, then admit air gradually. A constant circulation of air is likewise recommended for Roses at all times. Potassium sulphide, one ounce to two gallons of water, sprayed upon the plants, has proved effective. Gardeners, from long experience, have come to the belief that Rose mildew is induced by a weak condition of the plant, resulting from partial starvation, irregular or excessive watering, and undue exposure to draughts of cold air.

Downy mildew of Rose (*Peronospora sparsa*) differs in many ways from the one just mentioned. It is less easy to detect, and, being more deeply seated, may do greater damage before detected than the powdery mildew. It is less easy to eradicate because it thrives within the substance, while the *Sphaerotheca* feeds superficially. The *Peronospora sparsa* is a close relative of many of the most serious mildews, as those of the grape, onion, lettuce, spinach and the rot of the Irish potato. The treatment for this is the same as for the anthracnose, to be mentioned later.

A Rose rust (*Phragmidium mucronatum*), similar to the rust of wheat, oats and other grasses, is not common in our section of the country upon indoor Roses. It is not unlikely that it may become a pest here, as it now is in California and other states in the Union. The pest has been so violent in its

attacks upon Roses in California that even the canes were blistered, the whole being covered with a mass of orange-colored spores. Cutting and burning all affected plants is the only safe treatment.

A kind of anthracnose (*Glœisporium Rosarum*) sometimes attacks the Rose when the leaves are small and pale, and the canes die at the tips. Sometimes the stems may be dead for a foot or more from the extremity. Not infrequently one branch will be dead clear to the base, and sometimes two or more are thus destroyed. The dead twigs show pimples quite evenly distributed over the surface, and from some, a minute, often curved, horn of a reddish color protrudes. When such stems are placed in a moist chamber the whole decaying surface becomes closely covered with numerous almost brick-red masses of spores, and the disease spreads rapidly through the adjoining parts of the twigs that seemed healthy when placed in the moist chamber. The fungus spreads so rapidly that in four days from the time spores were introduced into sterilized sections of Rose-twigs in test tubes the whole of the culture would be covered with the spore masses. This anthracnose appears to be new in that it has not been before studied microscopically.

Eel-worms, or nematodes, often work on the Rose, principally at and in the roots. These microscopic worms are in outline like that of an ordinary eel, and under the microscope are seen in almost constant motion. They cause an enlargement of certain parts of the roots, and by means of these galls or knots are easily detected with the naked eye when a plant is removed from the soil and carefully washed of the adhering earth. In order to get rid of the pest it will be of much assistance to know where the worms come from. They are, as a rule, much more abundant in warm climates than elsewhere, and the unusual abundance of these pests in northern gardens for the past two years is likely due to the lack of freezing of the soil. The greenhouse furnishes the proper conditions for the propagation of the eel-worms, provided they are there to begin with. This naturally raises the question of how they first get into the bed. They may be already in the roots of the plants, but in small numbers, when the plants are placed in the house. To guard against this the roots should be examined as closely as possible for the galls when the beds are set. All galled Roses should be excluded. The nematodes may come in with the earth. They infest a large number of kinds of plants, and it is an easy matter for them to come with the soil. Soil that has not been used for growing plants in the garden is not necessarily free, but may, if taken from a pasture or meadow, contain many nematodes. Then, again, they may be taken with the manure that is used. Cold, in excess, will probably destroy the worms, and likewise a high temperature is fatal to them. Both of these conditions may be impracticable to apply to the soil, the one being impossible in some cases, and the other too expensive. Rose growers might make the experiment of heating the soil of a small portion of the bed before setting the plants and satisfy themselves if such a treatment will pay. If manure is the chief vehicle of the worms it may be possible to grow Roses without so much of this constituent of the rose-soil. It may be that Roses can be grown with a burned soil to which all the necessary elements of plant-food have been added in the form of commercial fertilizer. The fact is, that the worms are doing much damage. When they are once in a plant there is no known way of driving them out. New conditions may induce the formation of new roots and a sickened plant may revive, but recovery is not usually to be expected. It is possible that some substance may be put upon the soil that, while not injuring the Roses, may kill the worms not already in the plants. Lime has been thus used and with favorable results. It is sprinkled upon the surface of the bed or better mixed with the soil, and each watering will tend to bring it in contact with the tender bodies of the worms. It is not unlikely that some fertilizing compound may be found that will furnish food for the plants, and at the same time deal a death-blow to the nematodes. Kainit may thus prove an efficient remedy, and it only remains for some enterprising rosarian to take the matter in hand and make a test of it. All that has been said regarding the habits of the Rose eel-worms applies equally well to those of the Violet, Coleus, Lantana, Bouvardia, Geranium, and a long list of other plants that are frequent or occasional victims to the same trouble. The treatment will vary with the nature of the plant, whether annual or perennial, woody or succulent, large or small.

FLORICULTURE FOR CHILDREN.

Mr. Robert Farquhar, of Boston, read a paper to show how and why children should be trained to love and cultivate flow-

ers. He argued that we could either stifle or strengthen the love of nature which was implanted in every young heart. If we encouraged and cultivated this love the mind of the growing child would be opened to the beauties of nature, and we should in this way provide for it a means of healthy exercise out-of-doors and a source of delightful recreation all through life. Children should have gardens of their own to care for, and they should be instructed in garden practice. They should be allowed to sow the seeds and care for the plants themselves, although they should be directed in all these operations. Florists who do business in villages and towns enjoy opportunities for doing effective work among children by explaining to their young visitors the manner of propagation by sprouting seed, or by setting out the young plant with its new-found rootlets from the cutting-bed. Subjects for explanation are ever at hand, and the florist who takes pains to instruct his little visitors will often make friends for life, and probably customers, too. The claims of children should never be forgotten in making up the lists of premiums for horticultural and agricultural fairs. Prizes should be given for plants grown by them and for bouquets and collections of wild flowers made by them.

Village improvement societies are doing excellent work in many sections. Some have distributed seeds and plants to the school children with most satisfactory results; florists should profit by this example. Any florist who so wills can begin an effective village improvement society of his own without expense of time or money. Usually the unsalable surplus of bedding-plants is thrown away at the end of the planting season. Why not give them away to the school children? Let the teacher make it known that at a certain time the distribution will be made. When the eager company has assembled it will take but a few minutes of time to give one or more plants to each. Could a happier disposal of stock, useless to the florist, but valued by the children, be made? The satisfaction experienced will more than pay for the inconvenience, and the giver has made an effective and enduring advertisement. Unquestionably, the greater number interested in floriculture the larger will the demand become for both flowers and plants. Children soon grow up into patrons and are worth cultivating if for business only.

Members of this society should make a united effort to have the claims of floriculture for children, and kindred subjects, recognized in all our schools.

The merchants, lawyers and ministers who usually make up our school committees rarely seek to influence education in the interests of horticulture or agriculture. It is book-learning from beginning to end. As a consequence, we have a large surplus of middle-men, and men who live by their wits. Small wonder, then, that a large proportion of our best all-round gardeners originally came from abroad. In most European countries school-life fosters a practical acquaintance with Nature. Our children here love the beauties of nature as dearly as any, and our schools should foster such love instead of checking it. As an agricultural country America stands in the front rank, and the prosperity and wealth of the whole country depend upon the prosperity of those who till the soil; but these facts are entirely lost sight of in our schools; at least, no training is provided which bears directly upon them.

On this side of the Atlantic we justly pride ourselves upon being in advance of European countries in most attainments. We are very far behind many of them in the important matter of horticultural education of children. In France there are over twenty-six thousand primary and elementary schools where gardening is practically taught in gardens surrounding the school-houses.

In Austria there are about eight thousand of these schools, with from one-half to two acres each of cultivated land around them. The grounds in the rear may be found planted with a large variety of trees; at the sides and front are shrubs and flowers. One may see the teachers and pupils mingling together, studying interesting lessons based upon these plants. It has been said that boys will sooner injure a tree than cultivate it, but Mr. Farquhar said he should not be afraid to risk his trees with the boys educated at such a school.

Our country is young, but it is rich and progressive. The plain old school-buildings are going, and elegant buildings, with costly appliances, are taking their places. But we should not be content with fine buildings, large playgrounds and good teachers. In this country more than any we need the proper setting of ample grounds, filled with shrubs and flowers to bloom from earliest spring till winter. Instead of books alone, we should see to it that our children have ample opportunities for enjoying a lesson from the book of Nature.

Notes.

The tenth regular meeting of the American Horticultural Society will be held at Chicago on September 28th, 1892.

The Minnesota Forestry Association will hold its annual meeting at Minneapolis on the 8th of September, and the American Forestry Association has been specially invited to send a delegation. A large forest-reservation has been asked for in Minnesota, and it is a good field for energetic work.

The bulbs of the Ascension Lily (*Lilium candidum*) should now be lifted if new beds are to be made. In fact, they should have been lifted in this latitude nearly a fortnight ago, or as soon as the tops were dead and before new roots begin to start. If the lifting is delayed until later, leaves will have been formed which remain green all winter, and the plants will receive a check which they will not get over in a year.

Messrs. Sander & Co. have dropped the varietal name *Schroederiana* which was formerly attached to a good variety of *Dendrobium Phalaenopsis*, because many other varieties—some of them superior—have been introduced by this firm. *D. Phalaenopsis* is now known as a very variable yet very beautiful and well-marked Orchid, and a plant of it in Kew just now has twelve flowers on a single spike with numerous buds.

One of the famous great ancient Oaks of the Home Park, at Hampton Court, near London, was recently almost entirely destroyed by fire, although the firemen of the palace were aided in their efforts to save it by the steam fire-engines of Kingston and Surbiton. In local belief this tree was eleven hundred years old; it was declared to be one of the eight largest trees in England, and it measured thirty-three feet in circumference.

In answer to a question, Mr. H. E. Chitty, of Paterson, New Jersey, stated at the recent convention of the American Florists that the best twelve Carnations are: Lizzie McGowan and Silver Spray, white; Grace Wilder, pink; Daybreak, soft pink; Tidal Wave, deep pink, bordering on magenta; Portia and President Garfield, scarlet; Ferdinand Mangold, crimson; J. J. Harrison and American Flag, variegated; Golden Gate and Buttercup, yellow.

The Cardinal-flower which now gleams from the tangled foliage along the banks of mountain-streams, or almost startles one who comes upon it amid the rich green of moist meadowland, will thrive luxuriantly when lifted and transplanted to higher and drier soil. Some flowers, however, never look happy in trim gardens, and *Lobelia cardinalis* is one of these. Something of the wild grace and charm which invests it is lost when it is removed from its natural surroundings.

A late number of *The Garden* contains a good colored plate of the Azalea Hexe, which is a hybrid between the Chinese *A. amœna* and one of the Indian Azaleas. There have been a great many hybrids between *A. amœna* and different kinds of Indian Azaleas, and since *A. amœna* is a perfectly hardy plant it would be interesting to know how many of these hybrids have been tried out-of-doors in this country. These smaller-growing Azaleas are of neat habit, forming dense twiggy bushes, and they flower with great freedom.

In the early days of Spanish rule the Vine was extensively cultivated in Honduras, and excellent wine was manufactured there. But the very excellence of the product was the ruin of the industry, for, in the belief that Honduras competition might crowd Spanish wines out of the market, an edict was sent out from Madrid that every Vine in the dependency should be plucked up by the roots. This edict is still in the possession of the Honduras Government, and it is only of late years that Vine-culture has again been established in the country.

"Under the direction of Colonel Frank J. Parker, of Walla Walla," says a Chicago paper, "a large amount of Flax-seed will be planted in Washington and carefully cultivated for exhibition at the World's Fair. The flax will be shown in all stages of growth and manufacture. The fibre will be sent east to be worked up into souvenir fabrics, which will be exhibited in the Agricultural Department and in the Washington State Building. Colonel Parker, who is an enthusiastic advocate of Flax-culture in the state, will bear the expenses of preparing and making the exhibit."

What promises to be one of the finest drive-ways in the country has just been begun at Bayfield, Wisconsin. "This new boulevard," says a western paper, "will extend from Washington Avenue, directly in front of the Island View Hotel, along the lake-shore for about eight miles to the Redcliffe Indian Reservation, and will afford a magnificent view of Bay-

field Harbor and the Apostle Islands for the entire distance." It will be called the Dalrymple Boulevard in acknowledgment of the fact that it has been secured, after several years' efforts, by the diligent exertions of Mr. W. F. Dalrymple.

With regard to the Rose display at the current Horticultural Exhibition in London a correspondent of *Gartenflora* recently wrote: "What can I say about the Roses which fill the entire centre of the main hall? This exhibit of Roses was divided into nineteen classes, and one can only declare not merely that each class was richly represented, but that every blossom was worthy of special exhibition. Such symmetry of form and such splendor of color, as one expects only occasionally in exceptional flowers, were here universal. The first prize fell to Mr. F. Cant for a collection of seventy-two different Roses, among which each flower was not merely a picture but a model."

Mr. Carman writes in the *Rural New Yorker* that plants of a so-called White Blackberry, which he received from W. C. Raymond, Bridgewater, Vermont, have ripened fruit. The fruit is of medium size, and the drupelets large and comparatively few. The color is hard to describe, being not white but a pale whitish purple. The berry is peculiarly sweet, juicy and delicious, and as distinct in quality from ordinary blackberries as the flavor of the red raspberry is distinct from that of a blackcap. The plant passed through the winter well, although the last winter can hardly be considered a test. The thermometer drops occasionally to thirty degrees below zero in the part of Vermont where this plant was originally found, and it is therefore probably hardy.

Professor Bailey makes an appeal in *Science* for a broader field for botany, which has become restricted until it is little more than the science of wild flowers. But now that the doctrine of evolution has added a new purpose to the study of natural objects, cultivated plants are especially valuable for the examples they give of variation and of the effect of modified environment and selection. The common view that the variations in cultivated plants are anomalous, and therefore uninteresting, is erroneous. But apart from the fascinations which the cultivation of plants has in the direction of science, this cultivation demands the attention of botanists because horticulture ought to be nothing more than the application of the principles of botany. The fact is that it is quite impossible to separate horticulture and botany by any practical test, and, therefore, a department of botany should comprise laboratories, botanic gardens, greenhouses, orchards, vegetable and ornamental gardens, all maintained for purposes of active investigation rather than as mere collections. Botanists too often care little for gardening, and horticulturists are too often apt to underrate the value of scientific investigation. No man who does not unite scientific knowledge and practical training can appreciate the needs of botany in its broadest sense. No one can be a specialist in all subjects, but the ideal occupant of a chair of botany in the university of the future will have the genius to encourage and direct the work of specialists in every direction, and not until then can the science be actively presented to the student in its fullest possibilities.

The oldest herbarium in the world is in the Egyptologist Museum at Cairo, and consists of an inconspicuous collection of dried portions of plants. These portions of plants and flowers were taken from wreaths and garlands in the coffins with mummies, where they were placed by the ancient Egyptians as death-offerings, and from edible plants which were set in earthen vessels on the floor of the sepulchre as the furniture of the last resting-place of their beloved ones. Many of these floral remains are so well preserved that after being treated with warm water they can be handled like modern herbarium specimens. The colors, too, are preserved in a remarkable way. The most important matter in connection with these plants is their age. The remains of funeral-food are found in tombs as far back as three thousand years before Christ. Five hundred years later grains of mustard-seed, capsules of flax-seed, gourds, lentils, beans, figs, pine-needles, juniper-berries and other edibles are found. The richest acquisitions in leaves and flowers to the herbarium were made from the tombs constructed between the eighteenth and eleventh centuries B. C. Among the flowers chiefly employed in floral decorations for the dead were the blue and white Lotus, the red Poppy, the Oriental Hollyhock, Crown Chrysanthemum, Safflower, Pomegranate-flowers, Willow-leaves, Grasses and Peppermint. Celery-leaves came into requisition later, and onions, leeks and garlic played an important part in the offerings to the dead. One of the general conclusions drawn from this herbarium is that Egypt has sustained no appreciable climatic changes during the last four thousand years.

The Shad-bush (Amelanchier alnifolia) in Washington, Fig. 69	415

The Western Shad-bush.

THE genus *Amelanchier* is a natural one, closely related botanically to *Cratægus*, from which it differs in its long, strap-shaped petals and principally in the nature of the ovary, which is usually five-celled, each cell being incompletely separated into two chambers by the development from the back of a partial or false division, so that the fruit, which is a little fleshy pome or apple, appears to be ten-celled, each cell containing a seed with a cartilaginous chestnut-brown mucilaginous coat. Frequently, however, there are only five seeds in the fruit, owing to the abortion of one of the two ovules which the ovary contained in each of the original five cells. To its juicy flesh and thin-shelled seeds is due the superiority of the fruit of *Amelanchier* to that of *Cratægus*, in which the flesh is dry and mealy, and the stones, which make up a large part of the fruit, are large and thick-walled. In fact, the fruit of the Thorns is barely edible, and, unless the stones are removed, very indigestible.

Amelanchier has not been differentiated into a large number of species, as is the case with many of the genera of the Rose family, to which it belongs, and only five or six species with a number of varieties are distinguished, all of them bearing such a close resemblance to each other that it is not always easy to recognize them or to find stable characters by which to distinguish them. The genus is widely and quite generally distributed, however, through the north temperate zone; it occurs in the northern and temperate parts of eastern and the mountain-region of western North America, in Japan and central China, in Asia Minor, the Caucasus, southern Europe and northern Africa, but is not found in the great mountain-region of central and southern Asia, to which it might naturally have extended. Europe possesses one small shrubby species, which abounds also in north Africa and in Anatolia; a second species inhabits the Orient, and a third is widely

distributed in central China and in Japan. This is the *Amelanchier Asiatica*, which such careful observers as Miquel and Maximowicz considered merely a variety of the arborescent Shad-bush of eastern North America, where there are two species. These are *Amelanchier Canadensis*, with several well-marked varieties, and the beautiful *Amelanchier oligocarpa*, a shrub of the extreme north, which, as a garden-plant, is one of the most desirable of all early-flowering North American shrubs.

In the year 1804 a party of United States soldiers, under the leadership of Captains Lewis and Clark, commenced the first overland journey from the shores of the Atlantic to those of the Pacific Ocean; on the waters of the upper Missouri River they were able to eke out their scanty diet with the large and delicious Service-berries, which they found in great profusion along their route. This was the fruit of the western Shad-bush, or Service-tree (*Amelanchier alnifolia*), which first appears in literature in the history of this famous and important expedition. The specific character of the plant, which was confounded with the species of the eastern states, was not recognized in these early days, and although it was introduced from Oregon into English gardens by David Douglas in 1826, it was not until some years later that Thomas Nuttall, who had found it in the northern Rocky Mountains, gave the western Shad-bush the rather inappropriate name still used to designate it.

Amelanchier alnifolia is usually a low shrub with spreading stems only a few feet high; sometimes it sends up from the ground a cluster of tall thin stems, or occasionally, under exceptionally favorable conditions, it forms a slender tree thirty to forty feet in height, with one straight trunk eight to ten inches in diameter.

In different parts of the country *Amelanchier alnifolia* varies in a striking manner in the size and color of the leaves and in the amount and color of the pubescence which covers their under-surface while young as well as the shoots. These are generally oval to nearly circular in outline, rounded or rarely acute at the apex, rounded or slightly heart-shaped at the base, and coarsely toothed above the middle; usually they are dark green and membranaceous or slightly coriaceous, although in the dry interior parts of the continent they are much thicker and gray-green on the two surfaces. The leaves vary from an inch to an inch and a half in length and breadth; they are rather inconspicuously veined, and are borne on short slender stalks. The flowers, like those of all the *Amelanchiers*, are produced in short erect racemes, and are smaller than those of the Shad-bush of the eastern states, the pure white petals varying from a quarter to an inch in length. The fruit ripens in different parts of the country from June to September; it is subglobose, from a half to nearly an inch in diameter, dark blue, or sometimes nearly black, covered with a beautiful glaucous bloom, and very sweet and juicy.

The western Shad-bush grows over an immense territory; at the north it is found in the valley of the Yukon River in latitude 62° 45'; it extends south over nearly all the mountain-ranges of western America, ranging eastward to Colorado and Nebraska and through the Saskatchewan and Manitoba to the western shores of Lake Superior and to the northern peninsula of Michigan, where forms occur which are not always easy to distinguish from varieties of the eastern *Amelanchier Canadensis*.

In the interior of the continent *Amelanchier alnifolia* is confined to high elevations, sometimes ascending to 10,000 feet above the level of the ocean, where it occurs near the borders of alpine meadows or covers dry hill-sides with thickets not infrequently hundreds of acres in extent. It is in the valley of the lower Columbia River in rich bottom-land often inundated, or on the small prairies which are common in Washington near the shores of Puget Sound, that the western Shad-bush grows to its greatest size. In such situations it occupies the ground to the exclusion of other shrubs, or is associated with the Oregon Crab-apple, the Hawthorn and the Choke-cherry in dense masses about the margins of the forests of larger trees.

The fruit of the western Shad-bush, like that of all the plants of the genus, is sweet and of excellent quality, as many travelers through the western wilds of North America can bear testimony. Many a party of half-starved explorers and prospectors have been kept alive by Service-berries, which have been always an important source of food-supply to the Indians of the west, who visit every year the localities where the plants are abundant, and gather the fruit for winter use, first crushing it, and then, having dried it spread out on stones or bark, packing it in sacks.

As a plant with which to decorate our gardens *Amelanchier alnifolia* is less desirable than the larger-flowered and larger-growing eastern *Amelanchier Canadensis* and its varieties; it is perfectly hardy, however, and, like all *Amelanchiers*, is easily raised from seed, the seedlings displaying considerable variation in the size and quality of their fruit.

A figure of the flowers and fruit of the western Shad-bush was published in an early number of this journal (vol. i., p. 185). The illustration in the present issue gives an idea of the habit of the plant as it grows under the conditions which most favor its development. It is from a photograph of a cluster of plants growing in gravelly and rather dry soil on a prairie, near Seattle, in Washington, for which we are indebted to Mr. C. V. Piper, of that city.

Water-towers in Massachusetts.

IN another column, Mr. Sylvester Baxter, describing the pleasure-grounds of Wakefield, Massachusetts, alludes to the great architectural beauty of the distant water-tower at Reading, a view of which can be had from the pleasure-grounds at Wakefield.

These water-towers are becoming marked features of the Massachusetts landscape. Every town of any considerable population has its water-works, and as the sources whence water may be drawn by gravity are exhausted, water-towers, or "stand-pipes," have become a necessity. They mark the hill-tops of eastern Massachusetts in every direction and form notable landmarks, but, with very few exceptions, they are not as beautiful as they are conspicuous. They are usually plain cylinders of iron thrust up into the air like enormous steam-boilers, much elongated and set on end, or like very thick, unsharpened lead-pencils, and they disfigure the landscape as a heavy, black perpendicular mark would deface a fine painting. Perhaps there is none more conspicuously ugly than that of Swampscott, the obtrusive presence of which must be very irritating to the summer residents along that beautiful and fashionable shore. Various other suburban communities offend in a hardly less degree. Malden, for instance, has a particularly bad one, unique in these parts, serving both as a tank and stand-pipe, and looking like a gas-holder, perched upon the summit of Wait's Mount, a fine rocky hill rising boldly out of the heart of the city. The offense is the more aggravating because several acres of the top of this hill have been reserved as a pleasure-ground. It is much to the credit of Boston that care has been taken to give architectural character to the several water-towers erected upon prominent elevations in various quarters of the city, the slender, white, minaret-like structure in Roxbury taking precedence in grace and beauty.

All persons of good taste and public spirit should unite in urging upon the local authorities the importance of true proportion, at least, in these structures; something which might be obtained at little or no additional expense. We condemn the Romans for their prosaic utilitarianism, as reflected in their public works. But their aqueducts and bridges had, at least, the merit of a simple grandeur, dignity and true proportion, while, in this age of iron, our useful constructions are apt to be obtrusively ugly.

It would be a wise reform to combine the monumental with the useful in our public works. It is now the exception when either our monuments or our structures of utility are constructed in accordance with sound architectural

principles. There are very few out of the thousands of "Soldiers," or "Soldiers and Sailors" monuments that have been erected since the civil war, which, in after years, a cultivated taste will not condemn. The useful and the monumental have, in many instances, been united with gratifying results in memorial halls, libraries, etc., and this custom is happily growing. One of the best forms of a memorial is a public pleasure-ground, and this idea is also obtaining popularity in many directions. There are also a few instances of memorial bridges—a most admirable form of monument.

If, however, either a community, or a beneficent individual, desires to erect an architectural monument, what better basis for such a structure could be found than that of a water-tower? Towers, pure and simple, have little use nowadays, and their erection in connection with public buildings is usually a waste of money which might otherwise be applied to much better advantage. But a water-tower is, in many commodities, an indispensable object. It could be either united with a public building, or it might stand apart in the midst of a public square, like an Italian campanile, or, erected upon a neighboring hill-top—in a park for instance—it would serve as a fine lookout point as well. In erecting monuments, merely as such, the lack of means adequate to the purpose is apt to give them a bare or scrumpy look. A water-tower must, of necessity, have ample proportions, and this fact would assure dignity and impressiveness if it were made the motive for a monument. Those communities which have monuments to erect would therefore do well to expend the money at their disposal for the purpose either to build a monumental water-tower, or, if they already have the misfortune to possess one of the ugly bare cylindrical monstrosities, to turn the fact to account by enclosing it with a suitably designed exterior of masonry—either of stone or brick, according to their means—embellished with suitable decorative work in the way of carving, sculpture and inscriptions. A monument of extraordinary beauty, either simple or elaborate in its decorative features, might thus be obtained, and its place in the esteem of the public, together with the honor accorded to the individual thus commemorated, would be heightened by the fact that the structure was of constant service in distributing throughout the community one of the most indispensable of life-giving elements—the blessing of pure and abundant water.

Civilizing Power of Floriculture.

THE "flower mission" reaches further and is more widespread in its effects than many comprehend. Nothing interests me more than to note the flowers in the windows of the houses of our working-people. Many of the women of such families are able to achieve real wonders in the culture of house and door-yard plants. They will very likely mispronounce—even ludicrously mispronounce—their names, but they surely have both common and artistic sense in manipulating them—more, I often think, than is displayed by many professional florists. What these unconscious artists know is gained by experience and neighborly consultation. It is all practical in the fullest sense of the word, and yet it all seems, and in most cases I am convinced that it is, filled with a very real æstheticism.

These people, though so fond of plant-culture, and no doubt strongly enjoying its successful results, are very generous. They enjoy quite as much the appreciation of their pets by others as they do the progress of their daily work in caring for their window-gardens or small yard borders. There is never a church meeting, fair or Sunday-school celebration to which they do not freely contribute of their floral stores; and in a long experience as a judge at city and rural flower-shows, I have never noted the existence of a keener appreciation of intelligent opinion upon the comparative merits of choice specimens of cut flowers or pot-plants.

Since the advent of the Tuberous Begonias, and the great awakening of interest in Cactus-culture, these village and suburban window-gardens have taken on a new interest for me. It is a constant pleasure to observe the houses as I pass, in winter and summer alike, and to notice the entrance of one

novelty after another. I live near a "junction village," where many mechanics and train-hands have their houses, and I am very sure that the men of these families keep their eyes open to the advent, in the cities whither they daily ply, of new plants, odd or beautiful, and secure specimens whenever the price is within their means. So far as I can learn, very few of these lovers of flowers buy through the mails or obtain their stock directly from commercial gardens or greenhouses. They are all expert at "rooting slips," and know whence to take them without disfiguring the stock-plant. With Begonias they quite understand leaf-propagation, and are expert in a rude way in the composition of potting-earth. The window-pots are protected from the sun, and by sedulous care unevenness of growth is obviated. But I notice that when one of these flower-loving families becomes able to build a cottage of its own, a corner bay-window is pretty sure to be provided for in its plan.

This love of flowers, of which I have been writing, seems to have something communal in its nature or origin, and does not in any notable degree extend far into the country round about. Only a few farmers' wives seem to care much for, or have any remarkable skill in, window or open-air floriculture. The truth probably is, not that they do not like flowers, but that they have much less time to attend to them. As for out-of-door flower-gardens, loose cattle, pigs, dogs and fowls make such a thing a matter of too strenuous policing to be practicable. Indeed, these dangers greatly limit and discourage the establishment of good kitchen-gardens, which are quite rare on the farms of interior New England.

I happen to know, however, of a flower-garden, the existence and success of which witnesses to the triumph which attends upon stubborn perseverance. It is the work of a farmer's wife and dairywoman who has her hands full of work and whose butter brings the top of the market. Her husband's farm borders on a cross-road with a narrow and not much-frequented track. Like all other roads, however, it is laid out three rods wide, leaving a broad grassy or weedy border. Fences on farms are now a thing of the past in the section referred to, except for the enclosure of pastures; and the road-sides are either cultivated or grassed to the edge of the wheel-track. In many places, at this time of the year, one may ride considerable distances along roads where the hubs of the wheels must brush the oats, rye or other grain in turning out to pass another vehicle. One of these road-sides close by an old homestead had thus been brought under cultivation in Potatoes, and a strip near the buildings was taken by the farmer's wife for a "posy garden." I have seen her working in it a long summer evening until it had become too dark to note the time by a watch. It is about one rod wide and five or six rods long, and I think it would puzzle any one to name any common flowering plant in cultivation that is not to be found there. There is not much apparent order or system in this garden, but it has become so famous that many driving out from the village go out of the way to visit it; and this indefatigable woman is deriving quite a neat income from the plants and flowers which she is called upon to supply for by-passers. She says it pays her much better than the dairy, which is the principal object of her daily care. It certainly confirms the truth of the adage, that "where there is a will, there is a way."

T. H. Hoskins.

The Lakeside Pleasure-ground at Wakefield, Massachusetts.

WHEN casually discussing the relation of the various lakes in the Boston metropolitan district to the question of public pleasure-grounds, in my account of a bicycle trip to the Waverley Oaks, I alluded to Lake Quannapowit, in the town of Wakefield, as one of the few examples of anything like an adequate dealing with the opportunity presented. That it has been done so satisfactorily in this case is mainly owing, I believe, to the public spirit of a wealthy citizen and to the fortunate location of an important county highway. The town of Wakefield, formerly South Reading, was named in honor of the late Cyrus Wakefield, the founder of the leading industry of the place—the manufacture of rattan goods. Mr. Wakefield did much to improve the town, then it adopted his name. He gave it a large and costly town-hall, and was chiefly instrumental in laying out and improving one of the most charming pieces of public ground possessed by a town of its size, numbering 6,982 inhabitants by the census of 1890.

The main county highway from Boston to Lowell, by way of Malden bridge, becomes in Wakefield, as in most of the places through which it passes, the main street of the town,

the most populous part of which is pleasantly situated between two lakes, something like a mile apart; Crystal Lake, the smaller of these, lies to the southward of the village against a pleasant range of rocky and wooded hills. It presents a charming appearance from both the Boston and Maine Railroad and the main highway; the railway runs between the lake and the street, which is considerably above the water-level and commands some beautiful glimpses between the intervening houses—a fact which it would be well to take advantage of by providing an open space from which a view of the water might always be obtained. A most attractive feature of this lake is a pretty little rocky islet, covered with trees.

Lake Quannapowit lies at the other end of the village, and the common is designed with reference to this fact. As it approaches the lake, Main Street broadens considerably and gives opportunity for the beginning of the public ground, which takes the shape of a large triangle with its base on the lake-shore. The first section is a wedge-shaped piece of ground containing a few hundred square feet. This is walled about with rough rock about eighteen inches high, I should say, entirely mantled with a luxuriant growth of Japanese Ampelopsis. At the broad end, toward the lake, is a large rock-rimmed basin, screened on the north by a high, irregular-shaped wall of rough rock, rising to a height of perhaps four or five yards. At the centre of this wall is a handsome Elm. A rich and tangled growth of Bittersweet clammers over the wall and up into the tree, thus uniting it with the structure of a fountain, which, rising from the basin, sends a fine spray over the adjacent grass and foliage, keeping it a rich full green. The only questionable feature about this delightful bit of ground is the formal flower-bed which occupies the centre of the raised grass-plot within the triangle with some garish Geraniums and foliage-plants—altogether too artificial in appearance for the unconventional character of the design. A group of flowering shrubbery would be better.

Beyond the road which cuts off this triangle from the continuation of the public ground is the old-fashioned New England Common, here a large grassy space widening out toward the lake, tree-shaded, and bordered by a low fence of simple design. This piece of ground could, in its simple dignity, hardly be improved. The common, again, is separated from the grounds bordering the lake by a street, upon which, facing the town and cornering upon the lakeside grounds, is a large and handsome new church of gray stone—a feature that greatly helps the scene with its picturesquely rich and stately architectural element.

The grounds on the lake slope gently down from the street to the shore. Very appropriately this area is simply a broad stretch of lawn, with no trees to interrupt the view of the water, to which it thus carries the eye by the pleasing transition of a broad sweep of greensward. Fortunately, the town has had the good sense and good taste to remove a very ugly brick fire-engine house that, until recently, stood here. An ornate music-pavilion is now the only structure upon the grounds; it offers no obstruction to the view, which it only serves to accent.

This attractive scene gives Wakefield its most distinctive character. The lake, thus cherished and beautified, plays an unusually important part in the life of the place. There is bathing in its waters; boating, canoeing and sailing on its surface in the summer; skating and ice-boating in the winter, besides band concerts, promenading and driving on its shores.

The view up the lake deserves rank among the notable park scenes in the country. There is a vista of something like two miles of sparkling blue water to the northward, with a shore-line just irregular enough to prevent monotony, but without diminishing the effect of largeness—the water-area showing for the full value of its length and breadth. White-sailed yachts skim like swallows over the surface, and row-boats and canoes glide gracefully about.

Beyond the end of the lake, on the upland to the left, cluster the roofs and spires of Reading, the parent town of Wakefield, and, seemingly from the midst of the place, rises a great water-tower of a decided architectural character. In the distance, from across the water, its high and massive shaft with a finely proportioned roof, tapering like that of a mediæval turret, say at Nuremberg, is most impressive, and dominates the surrounding edifices of the town with something of the grace and majesty of a great cathedral tower in an Old World city.

The main street, or county road, on its way northward to Reading, turns to the right and follows the easterly shore of the lake. Between the street and the water the lawn-like character of the grounds continues for some distance, giving to the margin of the water a refined touch in keeping with its surroundings. There is, however, too great a uniformity in

this smooth expanse of lawn extending along the shore. The central space should, of course, be kept smooth and broad, and as it is, the plain simplicity of the whole is vastly preferable to the tawdry fussiness of floral bedding effects. Here, however, by the massing of varieties of flowering shrubbery on both the right and left of the lakeside section, and on the strip between the road and the water, a pleasing effect could be produced something after that of the Fenside, on the Back Bay Fens. The expense of caring for so much lawn would also be saved. In carrying out a work of this sort it would be well, of course, to obtain the advice of a landscape-architect.

A number of pleasant-looking places, including several simple, old-fashioned-looking houses with ample grounds, stand on the street bordering the lake. On the water-side of the road there are one or two boat-houses, and a little boat-landing is seen now and then. As the road continues it loses its suburban character and becomes distinctively rural; the strip of ground between the highway and the water is diminished to a few feet. There is a good fringe of trees and wild shrubbery along the margin. It is said to be the intention to widen the street gradually and, by filling in, make a broader strip of ground along the water-side. If this should be done it would be well to retain the wild shrubbery, emphasizing, however, its present character by planting all the native species natural to such a habitat.

It would also be well to secure the westerly margin of the lake, so far as possible. On that side, at a point near the town, there is a cemetery with its white marble gravestones and monuments gleaming under the trees—less offensive than most places of the kind. Looking back toward the town the view at that end of the lake is picturesquely attractive, with the fine expanse of public grounds and the handsome great stone church. At that end is the principal landing-place, and a little fleet of sail-boats lies moored off shore. A huge ice-house, with its galleries painted dark brown, stands near by, and is not an unpleasing example of utilitarian construction. Along the westerly shore, here and there, are other great ice-houses like barracks; some of them are brilliantly whitewashed and are altogether too prominent.

The road, in its course beside the lake, commands a succession of fine views over the water. Near the northern end of the lake a pretty brook comes gurgling out through a thicket, the modest beginning of the Saugus River. Beyond is a little beach by the roadside, with a watering-place for horses and cattle.

I must note a pretty effect that caught my eye at a railway crossing on my way home by bicycle. The county highway runs very near the Boston and Maine Railroad. At a crossing near the southerly limits of the town of Wakefield I was struck by the very graceful effect of a growth of Virginia Creeper clambering over the sentry-box-like little house for the flagman, and thence up the tall post bearing the usual sign of "Look out for the engine while the bell rings!" converting it into a really beautiful feature by the simple sweep of the carelessly drooping sprays of foliage. Such effects are very common at railway crossings in Germany, but are rare enough in this country, and especially on the Boston and Maine Railroad.

Boston.

Sylvester Baxter.

Late Summer Flowers on the Prairie.

THOUGH many species of *Allium* are cultivated for food, some have found a place in the flower-garden. A wild species common on the prairies may be classed with the ornamental kinds, especially when seen in masses. In late summer the Nodding Wild Onion (*Allium cernuum*) decks many fields with showy flowers. The triangular scape, a foot or two high, curves abruptly near the top, and carries a roundish umbel of thirty to fifty flowers in a nodding position, which has given it both its common and botanical name. They are mostly rose-colored, but pink and white kinds are numerous. This imparts to a field a variegated appearance, bright on the whole, since the reddish hues prevail. They are often in such quantities and grow so thickly that little else is noticeable where they stand. They are not easily exterminated, and maintain their place where most of the native plants have disappeared, still flourishing on the commons or in vacant lots in the more thinly peopled sections of the city and in the suburbs. They are common in pastures where the feet of cattle have crushed out the life of less stubborn plants, or where the prairie grass has been replaced by cultivated kinds. In some localities they have evidently increased under such treatment, and taken the place of those which have yielded. Their bulbous root serves them admirably in this respect, and bears much rough treatment before its vitality is destroyed.

Sometimes the Spiked *Liatris* (*L. spicata*) shares the ground with it, or is seen apart in other masses quite as extensive. In either case it forms a striking picture. With a long cylindrical spike of rose-purple flowers lifted a foot or two above the *Allium*, the combined effect of the two when growing together is very fine. Nearer the ground are seen the lighter-colored, roundish flower-clusters of the *Allium*, while over them stand the brighter, wand-like clusters of the *Liatris*. Though the leaves of the *Liatris* are very numerous, they are not long enough near the upper portion of the stem to seriously hide the flowers of its humbler companion, but being close and very narrow often furnish them with a fringe-like setting. The *Liatris* also has a thick, solid root or corm, and retains its hold quite well upon its native soil, though disappearing sooner than the Wild Onion from fields where the indigenous grasses have been supplanted by foreign species.

Another showy plant of a different habit, *Hibiscus Moscheutos*, the Swamp Rose Mallow, is in bloom at this season, and lasts till September. Though common in brackish marshes by the sea, it is much less familiar to those dwelling at a distance from tide-water. It is found in the swamps and by shallow ponds near the southern end of Lake Michigan. The rose-colored flowers, expanding five or six inches, exceed in size any flowers here except the Water-lily and the Yellow Nelumbo. The branching stems are from four to eight feet high, and are abundantly provided with handsome dark green leaves, which are soft and velvety. The large buds are as attractive as the flowers, excelling them in one respect, since the flowers are of short duration, while the buds are prominent for several days. In this region the Rose Mallow does not usually grow in water, but on sandy and muddy shores, which are overflowed in the wet season. It does well by the drier borders of the ponds, and remains in localities somewhat remote from them, where the swampy lands have been drained. It may be found interspersed with *Cornel*-bushes, or with a background of low trees and climbing vines. It readily takes to cultivation, and is a fine ornament for the garden.

Englewood, Chicago.

E. J. Hill.

New or Little-known Plants.

Cypripedium Chamberlainianum.

THIS new *Cypripedium*, which was the occasion of considerable comment among Orchid-growers when it was first announced for sale early in the present year, was imported from New Guinea by Messrs. F. Sander & Co. It is a beautiful species, besides being so distinct that it was described originally as belonging to a totally new section, and it really has few characters in common with *C. Rothschildianum* and *C. Stonei*, although it is classified in the same group with them. The plant has been described in former numbers of GARDEN AND FOREST, and our present purpose is merely to invite attention to the illustration (see page 413) from a photograph kindly sent us by Mr. Robert M. Grey of a specimen which flowered something more than a month ago for the first time in America, so far as we are aware, in the collection of H. Graves, Esq., Orange, New Jersey. The species is robust and very floriferous, and native specimens are said to produce from twelve to twenty flowers. The plant from which our illustration was taken was weak, but it produced six flowers. The dorsal sepal is primrose-yellow, veined and speckled with vinous brown. The petals are much twisted and of the same color. The lip is much inflated, a bright rose-purple and primrose about the opening and base. Altogether, *C. Chamberlainianum* seems to justify all the enthusiasm which its introduction kindled.

New Orchids.

DISA INCARNATA, Lindl.—After being known for upward of half a century, this Madagascar species has at last been introduced to cultivation, and flowered with Messrs. W. L. Lewis & Co., of Southgate. The flowers are of a bright cinnabar-orange, except the dorsal sepal, which is deep yellow, with bright red spots.—*Gardeners' Chronicle*, May 14th, pp. 618, 619, fig. 88.

PHALENOPSIS × *AMPHITRITE*, Kranzlin.—A pretty hybrid raised between *P. Stuartiana* and *P. Sanderiana*, the latter being the pollen parent. It bears a considerable re-

semblance to *P. Sanderiana*, modified in the direction of the other parent. It is not stated where it originated.—*Gardeners' Chronicle*, May 14th, p. 618.

CÆLOGYNE CUPREA, Kranzlin.—A species allied to *C. speciosa*, Lindl., but with smaller glabrous flowers, which are copper-colored. It flowered with Monsieur Wendland at Herrenhausen from plants imported by Messrs. F. Sander & Co., of St. Albans.—*Gardeners' Chronicle*, May 14th, p. 619.

ONCIDIUM GRAVESIANUM, Rolfe.—An elegant *Oncidium* allied to *O. crispum* and *O. prætextum*, but with much narrower petals, which impart a very distinctive appearance to the plant. It bears large branching panicles of golden yellow and brown flowers two inches in diameter. It was imported from Pernambuco by Messrs. F. Sander & Co., of St. Albans, and received an award of merit from the Royal Horticultural Society on April 19th last.—*Gardeners' Chronicle*, May 21st, pp. 650, 651, fig. 94.

CYPRIPEDIUM × EVENOR, Hort.—A hybrid raised from *C. Argus* crossed with the pollen of *C. bellatulum*, with foliage much like the former, and a flower resembling that of *C. × Marshallianum*. It was exhibited by Messrs. James Veitch & Sons, of Chelsea, at a meeting of the Royal Horticultural Society on May 17th last, and received an award of merit.—*Gardeners' Chronicle*, May 21st, p. 664.

CYPRIPEDIUM × EURYLCHUS, Hort.—A hybrid raised from *C. ciliolare* crossed with the pollen of *C. hirsutissimum*. The petals are elongated and deflected, rose at the tips, greenish at the base, spotted with purple, the upper sepal and lip being greenish, shaded and spotted with purple. It was exhibited by Messrs. James Veitch & Sons at a meeting of the Royal Horticultural Society on May 17th last.—*Gardeners' Chronicle*, May 21st, p. 664.

DENDROBIUM × NESTOR, O'Brien.—A hybrid raised from *D. Parishii* crossed with the pollen of *D. superbum*, and somewhat like a smaller edition of the latter. The flowers are three inches in diameter, the sepals and petals white, tinged with rosy lilac, and the lip with a large rosy purple blotch on either side. It was raised in the collection of C. Winn, Esq., of Birmingham.—*Gardeners' Chronicle*, June 4th, p. 718.

LISSOCHILUS GRÆFEI, Kranzlin.—A species allied to *L. streptopetalus*, Lindl., with an erect raceme of flowers, the sepals green, suffused with purple-brown, the petals pale yellow outside, brighter in front, and the lip pale yellow, with violet-colored side lobes. It flowered in the stove of Dr. Hugo Græfe, of Berlin.—*Gardeners' Chronicle*, June 11th, p. 749.

MASDEVALLIA × CASSIOPE, Hort.—A charming little hybrid raised from *M. triangularis* crossed with the pollen of *M. Harryana*. It is like an enlarged and improved form of the former, with the reflexed dorsal sepal and a considerable share of the brilliant coloration of the latter. It was

raised in the collection of Captain Hincks, of Thirsk, Yorkshire.—*Gardeners' Chronicle*, June 11th, p. 749.

CYPRIPEDIUM × CHRYSOCOMES, Hort.—A hybrid said to have been obtained by crossing *C. cordatum roseum* and *C. × conchiferum*. The flowers are very large, and light yellowish green, with some brown spots on the side lobes of the lip. It flowered in the collection of R. H. Measures, Esq., of Streatham.—*Gardeners' Chronicle*, June 18th, p. 781.

Foreign Correspondence.

London Letter.

FUCHSIAS.—An interesting lecture on Garden Fuchsias was read last week at the meeting of the Royal Horticultural Society by Mr. George Fry, the veteran raiser of many of the best varieties, and a well-known cultivator of them for the last sixty years. The early history of the Fuchsia as a garden-plant is now well known, how it was introduced a century ago

(1788) to London from Chili by a sailor, who gave it to his mother, who grew it in her cottage window at Limehouse, where it attracted the attention of a passer-by, and ultimately was purchased by the Messrs. Lee, of Hammersmith, the Veitchs of that period, for £80. Messrs. Lee's plant was named *F. coccinea*, by Aiton. Numerous seedlings were raised from it, and variety thus obtained, but it was not until the introduction in 1830 of a second species, namely, *F. fulgens*, that hybrids were possible. In 1855, Messrs. Henderson, of St. John's Wood, distributed the first of the varieties with white corollas, raised by a Mr. Storrey, of Newton Abbot, who unfortunately died soon afterward, without recording the origin of this new break. More recently, other species have been blended with the varieties previously raised, and there are now numerous distinct kinds, one might say hundreds,

Fig. 68.—*Cypripedium Chamberlainianum*.—See page 412.

many of them of exceeding beauty.

It is difficult to account for the want of popularity of the Fuchsia in England at the present time. There are certainly few gardens in which the genus is not represented, but one scarcely ever meets with a collection of Fuchsias as we do of Chrysanthemums, Pelargoniums, etc. And yet, no plants are more easily managed, none more elegant or more beautiful when well grown and flowered. I have a vase of the blooms before me as I write, a few shoots a foot long, thickly clothed with drooping crimson and white flowers, which have been in the room a week and are still fresh. It would be difficult to find any flowers better suited for vases than Fuchsias. They are not good nurserymen's plants, as they are so brittle that they pack badly, and the flowers are easily shaken off. Still, in the greenhouse, in the border, or even as wall-plants in the open air, they must always rank among the most decora-

tive of summer-flowering plants. In the conservatory at Kew, Fuchsias are grown as climbers; they are planted in a border below the side stages, and the stems are trained up and below the rafters of the roof, from whence the profusely flowered shoots hang in great abundance and have a very pretty effect. In the Temperate House the Fuchsias are trained to tall stakes twelve feet high, and in the summer they form narrow pyramids of bloom. Of course, the hardy kinds are also employed for summer bedding, a purpose for which when used with a little judgment and combined with suitable companions they are exceptionally well adapted.

Mr. Fry has grown perfect pyramidal specimens of the best kinds as high as fourteen feet. He recommends the sowing of the seeds, which are produced abundantly, much more than is at present practiced, as with ordinary care the plants will bloom when only six months old, and while all, or nearly all, the seedlings will be worth growing, variety, and probably some of superior quality, may be in this way secured. The arrangement of the stamens and pistil in the flowers of Fuchsia renders their cross-fertilization easy. There are a considerable number of species of Fuchsia which, in the hands of the skillful hybridizer, would probably yield good results in the shape of new varieties. Such species are *F. triphylla*, *F. decumbens*, *F. syringæflora* and *F. dependens*, none of which, so far as I know, have been bred from.

The cultural details given by Mr. Fry were pretty much the same as are known to all who have grown Fuchsias. He recommends shade for the plants when grown under glass, plenty of ventilation, plenty of water in the growing season, and a range of temperature from fifty to seventy-five degrees.

Mr. Fry's ambition had been to raise a Fuchsia with pure white flowers, but in this he has been forestalled by Messrs. Cocker, of Aberdeen, who raised a few years ago Countess of Aberdeen, which is almost wholly pure white, and is a very beautiful variety. There is a good collection of garden Fuchsias in the gardens of the Royal Horticultural Society at Chiswick, and at Kew there are altogether thirty-six true species under cultivation.

NEW PLANTS.—The following obtained certificates at the last meeting of the Royal Horticultural Society:

Lælia-Cattleya Ingramii, raised by Mr. Bond, gardener to Mr. C. L. Ingram, of Godalming, by crossing *L. Dayana* with *Cattleya aurea*. The plant, though small, was of promising appearance, and the flowers showed distinct traces of the characters of both parents, the *Cattleya* being most evident in the labellum, which was large and colored deep crimson; the sepals and petals were colored rose. *Cypripedium caudatum*, Luxembourg var. This was sent by Monsieur Godefroy-Lebeuf, of Paris. It is a very superb variety of a very handsome species, the flowers being large, with broad sepals, long tails, and the color a deeper shade of yellow than in the type, the markings of the labellum, etc., being as usual in this species. *Calanthe Sanderiana*, from the St. Albans nurseries, is a new species of considerable interest lately introduced from New Guinea. It belongs to the evergreen section of the genus, and resembles *C. veratrifolia* in habit, but the flowers are larger, with a peculiarly thick spur, and the color is mauve on the sepals and petals, crimson-maroon on the labellum. *Lælia Oweniana*, also from Messrs. F. Sander & Co., is a hybrid between *L. Dayana* and *L. xantheria*, in which the flowers are like those of the first-named parent, the sepals and petals white, the lip deep maroon in front, with a yellow blotch in the throat and a white disk-like area on the middle of the front lobe.

Sarracenia Farnhami, a hybrid between *S. Drummondii* and *S. rubra*, is another pretty addition to the cultivated varieties of Side-saddle plants. It has medium-sized erect pitchers, green in the lower half, crimson toward the apex, and prettily tessellated with greenish white and spotted. It was exhibited by the raiser, Mr. Farnham, of Loughborough.

The following Carnations were submitted to the committee as new, and obtained certificates: The Moucher (yellow), Old Coin (light brown, yellow and crimson), Salamander (rose), King of Scarlets (a very handsome full-flowered glowing red variety), Acme (yellow, with rose flakes), Duchess of Sutherland (Picotee, white, with rose margins), Nellie Bath (Picotee, yellow, with deep crimson edges), Mrs. A. Barrett (Picotee, yellow, heavily edged with rose). These were exhibited by Messrs. C. Turner & Sons, Slough, who have long held a foremost position among the raisers and cultivators of Carnations.

Mr. Rivers, of Sawbridgeworth, showed his new cherry, Emperor Francis, which was awarded a first-class certificate on account of the great size and rich flavor of its bright red fruits. At the previous meeting Mr. Rivers exhibited a collection of his best varieties of cherries, peaches, apricots and plums, which had been grown in his famous orchard-houses, and which astonished those who had not seen to how large a size these fruits can be grown under glass in England. He also obtained a certificate for a new plum named Late Transparent Gage, and which is remarkable for firmness of flesh, lusciousness and lateness, ripening at the end of August.

Buddleia Colvillei.—Mr. Gumbleton, of Cork, has been the first to flower this beautiful Himalayan shrub, specimens of the flowers having lately been forwarded by him to Kew. There is also a figure prepared from a specimen from the same source in the *Gardeners' Chronicle* this week. B. Colvillei was named and described by Hooker in his *Illustrations of Himalayan Plants*, published in 1855. He found it on the Sikkim Himalaya at an elevation of from 9,000 to 12,000 feet, where it forms a large shrub fifteen or twenty feet high, with lanceolate-crenate leaves six inches long, and large erect terminal panicles of crimson campanulate flowers an inch across. It is hardy in Mr. Gumbleton's garden, which is, however, favorably situated. From the altitude at which the plant is found it would, however, be safe to infer that it will prove as hardy in England as some of the Sikkim Rhododendrons which are found at the same altitude and are hardy here. I believe B. Colvillei will prove to be a good garden-shrub.

Cultural Department.

Some New Pears.

SOME new Pears are fruiting here, the first time this season, and notes upon them will be more interesting now than when the season is past. Some varieties prove themselves worthless in our region with their first fruits, while others are equally pronounced in the opposite direction. I find the greatest differences of opinion among individuals upon the quality and value of different pears. The Kieffer Pear is condemned as emphatically as it is praised throughout Pennsylvania, yet the points in its favor are so eminently good that it will win in its fight for a place in our orchards. As a market pear and for canning, I have only the warmest praise for the Kieffer as I know it here.

These notes on Pears were prompted by a very remarkable fact concerning the Lawson Pear. From stout, healthy trees, six years from planting, the first crop of fruit was set and ripened this summer. A more beautiful lot of pears was never seen, but not one out of the whole yield of two pecks contained seeds! The core was very much contracted and spongy. This seems to be a feature of the variety, as there is nothing abnormal to cause it temporarily. The trees are in the best state of health, and all the fruits are as near perfection as a summer pear can be. The Lawson deserves considerable attention as it is a very good early pear. The fruit is above medium size, broadly pyriform; skin, waxen lemon-yellow, with many green and brown dots, richly colored with bright crimson or red in the sun. The stalk is of medium thickness and length inserted at one side at an inclination, with a lip of flesh above and a depression on the under side; the calyx is partly closed in an open, even basin. The flesh is white, not very juicy, slightly granular, with a somewhat sweet, highly perfumed flavor, without seeds; it ripens from August 1st to August 20th. This pear will not keep very long after ripening as it softens at the core; this softening is most sudden in fruit

left too long on the trees. The fruit should be picked fully ten days before ripening. The points that will recommend this pear most strongly are size, color, firmness and fragrance.

To find if the seedless nature of this pear was known, I wrote to Wm. Parry, of New Jersey, who offers this variety. In reply he wrote: "A number of trees have fruited this summer and created a very good impression. We had not noticed that they were seedless, and cannot say whether ours were so or not, as our crop is now all gone."

The Early Harvest is another new Pear, ripening a week later than the Lawson. If it gives no better results elsewhere than it has given here, it would be better to abandon it at once. This is described in Parry's catalogue as "very firm, can be shaken from the tree like walnuts, packed and shipped to the market, ripening on the way and coloring up handsomely." All of which is quite true, but disappointment follows. The fruit is very firm even when fully ripe, so much so that the flesh is tough, and in all the fruits that passed under my observation the centres were soft through decay, and the taint of rottenness affected the entire fruit before even the color of ripeness appeared. Whether picked green or ripe,

four feet high, the lower portion furnished with dark green ovate-lanceolate leaves, terminating in large flowers, the purplish disks of which are prominent and cone-like—hence the popular name—and the drooping rose-purple rays about two inches long. It likes a good free soil, in which it makes vigorous growth, and is easily increased from seeds or by division of the plants.

Some of the Horse-mints, Monardas, notably *M. didyma*, commonly called Bee Balm, or Oswego Tea, and *M. fistulosa*, otherwise known as Wild Bergamot, are usually full of flowers at this time of the year, lasting, indeed, well into September; but, owing to a lack of moisture in July, our plants are not as fine as we have had them in past seasons. The good qualities of the plants, however, are still sufficiently manifest to elicit a word of commendation. They are fragrant perennials, from three to four feet high, and of erect habit. The flowers are borne in whorls at the extremity of the stem, and they are of an intense scarlet color in *M. didyma*, while those of *M. fistulosa* are light purple. There are a few other species, but those mentioned are the best of the group. Both plants make satisfactory progress in ordinary soil, but, if possible, they should be sheltered from the direct rays of the sun.

Fig. 69.—The Shad-bush (*Amelanchier alnifolia*) in Washington.—See page 409.

the interior behavior was the same. The quality of the pear in flavor and substance is very inferior.

Other varieties ripening later yielded their first fair setting of fruit in 1891, and show a good crop again this year. These are the Cocklin, Garber and Mikado, all of them of Sand Pear parentage; ripe in October and November. It is not probable that any of these will ever be considered fine for dessert, because of a certain coarseness combined with a lack of sweetness. They are all three to be classed with *Le Conte* in quality, and therefore not suited to the north.

State College, Pa.

Geo. C. Butz.

The Wild Garden in August.—II.

THE Purple Cone-flower (*Echinacea purpurea*) is very distinct and beautiful. Ample testimony of its attractiveness may be found in the fact that it was the second plant selected by the conductors of the *Botanical Magazine* for illustration in their great work. Although thus prominently brought to public notice so many years ago, it is still comparatively rare in cultivation; but it remains, nevertheless, one of the best plants of its class to be found in garden catalogues. The stems are about

There is no prettier sight in the garden at the present time than that afforded by a clump of the Flowering Spurge, *Euphorbia corollata*, growing strongly on the steep bank of a shallow pond. But this plant is very deceptive in a botanical sense, for what at a first glance seems to be the flower is only a series of bracts arranged around the real flower in the form of a calyx or corolla. The simple stem ascends to a height of about three feet, and is well clad with pale green, oblong leaves. The bracts are pure white, each cluster of five having the appearance of a spreading flower one-fourth of an inch in diameter, and these floral appendages are borne in immense numbers at the top of the stem, the inflorescence taking the form of a compound whorled umbel.

The Cardinal-flower, *Lobelia cardinalis*, is more at home on the lower ground hard by, where its erect racemes of glowing scarlet flowers have been a dazzling feature of the place for several weeks past, and where they will continue a brilliant attraction for some time to come. The blue flowers of *L. siphilitica*, the Great Lobelia, are quite as beautiful as those of its red-flowered relative, though not so lustrous. The plants resemble each other closely in habit and requirements, but *L. siphilitica* blooms later, the earliest flowers appearing

about the first week of August. There are white-flowered forms of these two species, which, while interesting as varieties, are not nearly so decorative as their original types. These *Lobelias* grow best in moist soil, and they may be quickly propagated by any of the methods commonly pursued in the case of herbaceous perennials.

Liatrix spicata is almost over, its career having been considerably shortened by the dry, hot weather. It is from two to three feet high, the numerous stems a trifle stiff. The habit is neat and compact, and the showy purplish flowers are freely disposed on the upper portion of each stem. This plant is most effective when grown in large patches, and it delights in free exposure to sunshine, and in soil of good quality. The same may be said of the Wild Senna, *Cassia Marilandica*, a most excellent plant, which flowered all through July and is still in full bloom. The stems of this *Cassia* are three or four feet high, erect, though slender, bearing alternate, pinnate leaves, and short axillary racemes of nearly regular, golden yellow flowers, the anthers of which are quite black, adding much to their beauty. The racemes are generally densely clustered at the stem, and the plant is best propagated from seeds.

The long racemes of purple Pea-shaped flowers produced by *Desmodium Canadense* are quite pretty, but the plant is large and spreads rapidly, requiring a great deal of space for its full development. Not so with the Missouri Evening Primrose (*Enothera Missouriensis*), which has been producing its enormous yellow flowers with great freedom since the latter part of June. It is seldom more than a foot high, the stems having a tendency to spread by courting the ground.

The various kinds of *Coreopsis* (Tickseed) make a lively show of color, chiefly bright yellows and rich browns. The plants vary in height from one to four feet, and the taller sorts require the support of stakes. *C. lanceolata*, *C. grandiflora* and *C. tinctoria* are the best species. The latter is an annual, but its self-sown seeds afford a generous supply of plants. *Centaurea Americana* is another desirable annual. It is about three feet high, the stems bearing handsome purple flowers, four inches in diameter, at the summit. The plants should be raised under cover in spring, and transferred to the open any time after the middle of June. *Eupatorium purpureum*, with reddish purple flowers, and *E. perfoliatum*, in which the inflorescence is whitish, are blooming profusely. They form ornamental groups from three to five feet high.

Cambridge, Mass.

M. Barker.

Some Little-known Annuals.

THE annual *Cupheas* are best represented by *C. lanceolata* and *C. silenoides*, plants of considerable merit, though not often to be seen outside of botanical gardens. They are worthy of a more extended use. The stems of each are from twelve to eighteen inches high, and bear large quantities of flowers during July, August and September. Those of *C. lanceolata* have two large, rich purple segments behind, and four smaller ones of paler color in front. The flowers of *C. silenoides* are very similar, except that all the divisions, large and small, are of the same dark purple color, the larger ones having margins of a lighter shade. Both plants are natives of Mexico, and they would probably repay some efforts in the way of hybridizing.

Emilia sagittata, better known as *Cacalia coccinea*, has been too much neglected. It belongs to the natural order *Compositæ*, and was introduced from the West Indies in 1799. The plant is of erect growth, about two feet high, and the stems and branches terminate with from three to six flower-heads of bright orange-scarlet color, and about half an inch in diameter. It blooms freely throughout the summer, and is most effective in masses.

The intense blue flowers of *Delphinium consolida*, borne in racemes from six to nine inches long, are very charming, and even in the driest season the plants bloom with surprising persistence. The stems are about two feet high, and fairly well branched toward the top. The leaves are deep green, and, being finely divided, give the plant a beautiful feathery appearance. *D. consolida* occurs freely in Europe, and was at one time highly esteemed in gardens abroad. The improved forms of perennial *Delphiniums* which have been produced in recent years were so detrimental to its popularity, however, that it is now rarely seen in cultivation; but it is slowly regaining its former position. There are many varieties, single, double and semi-double, in which the colors range through various shades and mixtures of blue, pink and white.

Trachymene cœrulea, sometimes called *Didiscus cœruleus*,

is a free-branching plant about eighteen inches or two feet high. The leaves are not imposing, but the compact, somewhat convex umbels of small, pale blue flowers are extremely pretty, and about three inches across. It is a native of New Holland, and was introduced in 1827.

Silene Armeria is a common European weed, but very decorative in our gardens notwithstanding. It is of erect habit, about eighteen inches high, branching profusely. The opposite, glaucous leaves are very smooth, of ovate-lanceolate outline, and rather pleasing to the eye. The large corymbose inflorescence is composed of showy pink blossoms, which are half an inch in diameter and produced in great abundance. *S. Armeria alba* is an excellent white-flowered variety, though hardly so ornamental as the species. The two plants are deserving of a place in every garden, and it is perhaps worthy of remark that both are said to spread rapidly in this country from self-sown seeds.

Sanvitalia procumbens is a desirable little gem, scarcely more than six inches high. The numerous stems are thickly clad with small ovate leaves, which form a close green ground for the dainty Daisy-like flowers an inch in diameter. The disk is dark purple in color, the ray florets rich golden-yellow and so formed that the entire circle appears to be regularly notched.

With the exception of the *Silenes*, which appear to give the greatest amount of satisfaction in slightly elevated portions of the rockery, all the plants here mentioned thrive best in the ordinary soil of garden-beds and borders. The seeds should be sown in spring, and placed in a greenhouse or frame where the heat is sufficiently great to exclude frost. The seedlings may be potted singly when large enough to handle easily, and finally planted outside when there is no further dread of cold weather.

Newton, Mass.

B. M.

Senecio Japonicus.—Besides hardy plants for border use there is now a large demand for suitable sub-tropical plants as a setting or background for aquatics. Many of these are only half-hardy, requiring to be replanted every year, a process which takes both time and money; consequently, all plants of this character which are hardy, love moisture and have a beauty of their own are worthy of notice.

The giant Groundsel of Japan, *Senecio Japonicus*, called in some catalogues *Erythrochæte palmatifida*, is not as well known as it deserves, though it has been in cultivation in the United States for ten years or more. It is, without doubt, hardy, and will thrive in any moist garden-soil. This *Senecio* is one of the handsomest of the genus, the plant being tall, five feet high, with large, much-divided leaves, each about a foot across, on long stalks from the root. The flower-stems are stout, sometimes much-branched, with large orange-yellow flowers three inches across, much like those of *Silphium* or single Sunflower, except that they flower in June. Our plants have flowered profusely this summer and are now maturing seed, few of which, however, have power to germinate. When given a proper place, with room to develop its roots within reach of plenty of moisture, *S. Japonicus* will prove very ornamental, either alone or associated with other plants. It starts very early in spring, and late frosts, which kill the *Polygonums*, *Astilbes* and other succulent shoots, have never in our experience injured this *Senecio* in the least.

South Lancaster, Mass.

O. O.

Begonia fulgens is a tuberous Bolivian species said to have been discovered in the same locality as *B. Baumannii*, and, like that species, it is especially interesting for its fragrance. *B. fulgens* proves to be a plant of dwarf growth with moderate-sized leaves, which above are of a deep emerald-green, with deep veinings of a lighter green, short abundant hairs and a satiny lustre. Underneath, the leaves have strong veins and are stained a vinous red. The leaf-stalks are short, and from these rise numerous pink flower-scapes to a height of, say, twelve inches. These each bear three or four very handsome pure carmine flowers, single, of good substance and five-petaled. The female flowers are in great preponderance. They are fragrant, but not so pronounced in odor as *B. Baumannii*. The scapes are slightly curved, and the flowers are pendulous. Owing to this habit this plant will not probably meet with much favor with the hybridizers, as the present fashion in *Begonias* is for rigid flowering-stems, holding the flower face up. But it is a beautiful variety, which will be welcomed by the fanciers of this species, among which are so many very interesting and beautiful plants. At the suggestion of Messieurs Lemoine, who introduced *B. fulgens* in the fall of 1891, one of the plants has been grown in the border in full

exposure to the sun. But this condition does not seem as favorable as the protection of a cool greenhouse, where the tuberous Begonias generally find their most satisfactory quarters in an average season in this latitude. Growers who have had much experience with this section of Begonias must be convinced that the plants require certain conditions for their welfare, and sometimes need careful attention, which can best be supplied in this climate of sudden changes when the plants have a certain measure of protection and are under some control.

Primula obconica grandiflora is the tempting name under which a French nurseryman offered, this season, the seed of a new *Primula*, said to be a hybrid between *P. obconica* and *P. cortusoides*. The claim made for this strain was that the flowers were not only larger, but that they had a wider range of color than in the *Obconica* type. A large lot of these plants, which are young, but very vigorous, fail to show much mixture of foreign blood with *P. obconica*. Among the plants are a limited number which show larger flowers than the type, say, an inch in diameter, and these somewhat in the way of *P. cortusoides*. The colors have about the usual range of mauves. Evidently the strain needs selection, but it is apparent that the best of the seedlings are an improvement on this valuable flower. A good admixture of *P. cortusoides* blood with *P. obconica* would apparently be a great gain, as it would probably give a touch of grace to the flowers, and might possibly produce a race which would be fairly hardy, and a hardy *Primula* of the free-flowering character of *P. obconica* would be a great gain. Out-of-doors the peculiar irritating quality of the leaves would not be so great a drawback to its culture. The strain under notice has these qualities rather more highly developed than in any seedlings previously grown by me, rendering them almost impossible plants to be grown in close quarters by any one who has a sensitive cuticle.

Aster Candelabra seems to be the most distinct new *Aster* of the year, and apparently worth cultivating. Usually *Aster* novelties vary only from the old types in coloring, with occasionally a slight change in form, the latest of which were the beautiful Comets introduced a few years since. This strain varies principally in the habit of the plant, it being much branched at the base with long stems in the way of a candelabra, whence it is happily named. Either for bedding or for cutting, this habit renders it well worth growing, as the plant is less compact than the usual type, and produces not only a less heavy effect, but furnishes more long-stemmed flowers. They are to be had in white, rose and violet, and are with reflexed petals. *Asters* in this locality are devastated by a large black beetle with an appetite many times larger than himself, and it is only by constant attention and almost hourly hand-picking that one can secure a crop of flowers. These insects are recent arrivals, appearing first some three years ago, before which the *Aster* crop was as much a thing of course as it is now uncertain.

Deforestation in Russia.

THE following article appeared in a recent number of the *Literary Digest*. It was translated from the *Preussische Jahrbücher* for July.

When treating of the Russian famine of 1891-92 in the April number of this magazine, we remarked that this was not to be regarded as a passing incident, but rather as the inauguration of a chronic condition of affairs traceable to unsystematic farming, to the general withdrawal of capital from the land for investment in manufacturing enterprise, under the ægis of a protective tariff, and to the general deforestation of the country, in great part to provide fuel for railroads and protected enterprises. The fatal consequences of this general deforestation are now generally appreciated, the shrunken state of the once noble rivers of the country, and growing aridity of the climate, affording evidence that can neither be overlooked nor gainsaid.

The regions of the mighty rivers, the Don, the Volga and the Dneiper, the great arteries of Russia, were formerly fringed with wide-spreading forests, along their whole upper and middle courses, which sheltered their sources and tributaries from evaporation throughout the year. These forests have now for the most part disappeared. Mile after mile the traveler sees nothing but low scrubs and melancholy stumps in unbroken succession; the "Mother Volga" grows yearly shallower; the steamers find scarcely seven or eight feet of water in mid-stream; and the ferries pursue their snake-like course from bank to bank in search of the ever-shifting channel. The Don, with its tributaries, is choked; the sources of the

Dneiper creep downward, and its chief tributary, the once noble Worskla, with a flow of some 220 English miles, is now dry from source to mouth.

The city of Poltawa lies on its banks, and it was at its mouth that the Swedish army surrendered to Peter the Great. This stream, which fertilized a broad region, supporting a numerous population, exists no more—not temporarily run dry, but with all its springs exhausted, so that in future it may be stricken from the map. The Bitjug, another river in the Don region, the upper course has wholly disappeared—valley and bed are filled to the banks with sand and earth. As if by magic, wide, fertile lands are buried under the sands, and whole villages desolated. "There has been," says Wiestnik Jewropy, "an unparalleled revolution of natural conditions, which threatens a great part of the country with the heat and aridity of the Central Asian Steppes. The present condition of our black-earth region is so serious, and its future so dangerous, that it cannot possibly escape the serious attention of the Government, the scientist and the husbandman, to whom the further development of the situation is perhaps a question of life and death."

There is perfect unanimity in attributing the threatening catastrophe to the denudation of the forests. Innumerable factories sprang into existence, and, in the absence of any systematic provision for coal-supply, they were erected in the heart of the forest, and, after having consumed all the available fuel within easy distance, their plant was actually sometimes transferred to fresh fields. Thus originated the system of wholesale destruction, which was liberally furthered by the network of railways built to maintain their communication with the great marts of commerce and provide generally for the transport of produce. For the past forty years thousands of locomotives and factories have been run almost wholly with wood without a thought being given to any provision for reproduction. The extension of the railways afforded an opportunity for extracting colossal fortunes from the "worthless" forests. These were the manufacturers' views also; so the fate of the Russian forests was sealed. "The machines have devoured the woods."

The recently passed law for the protection of the forests has come fifteen, twenty, or twenty-five years too late to avert the destruction of the agricultural region.

And the Government and people of Russia had already been warned. Forty-two years ago—that is, shortly after the famine of 1847-49—we find the following in a letter from the Charkowski Government to the Imperial Society of Economics: "There are now living people who remember when the present limitless expanse of sand-waste along the banks of the Dneiper was covered with almost impenetrable forest, interspersed with lakes, which have since dried up or are fast drying up. Our region is flat, deforested, and exposed to all winds. The fatal east wind finds no impediment, and brings ruin in its train. This wind will perhaps at no distant date prove fatal. The Grecian colonies went under probably from the same cause. Protect the forest; sow, plant forests, protect them with rigorous laws. The Volga and Don and all the rivers of southern Russia will be silted up and disappear unless the forests be protected."

More fatal even than the drying up of the streams is the cessation of the spring and summer rains. This is the immediate cause of last year's harvest failure, and on it even depends the current year's harvest. There have been local rains, but not nearly enough. This reversal of old conditions has been coming on gradually with the denudation of the forests; and emphatic warnings, as we have seen, have been uttered. The only result has been the appointment of commissions which have done nothing. Remedial measures on a large scale are now contemplated. Are they too late?

Correspondence.

The Violet Disease.

To the Editor of GARDEN AND FOREST:

Sir,—The article by Mr. Orpelt on Violet disease, on page 381, was of considerable interest to me. In view of the ravages caused by the Violet disease, in a letter written early last spring to the *American Florist*, I specially requested specimens of diseased plants for study at this station. Two shipments were received from a grower in eastern Massachusetts, who supplies the Boston market with Violets, and had in March about five thousand plants in one house. The leaves reached me in good condition, but soon turned brown and wilted away. At times the florist had thought that quite a

share of the disease was caused from the "sling" of the green fly, which did not develop until fall, when heavy dews and warm sunny days occurred. The plants of a neighbor of this Massachusetts grower have also been troubled with Violet disease, but he attributes it to coal-gas. The leaves in the house begin to dry up all around the edges, and finally the whole leaf becomes as dry as a bit of paper, and when a new growth of leaves appears they are affected in the same way. In the specimens of these plants a distinct bacterial disease was found.

We have just received another shipment of plants from Mississippi, from a woman who makes a specialty of growing Violets. The plants sent, she states, were quite healthy one week before shipping, but all at once they looked as if they had been scalded, and in a few hours were in a very badly browned up and wilted condition.

Mr. Orpet states that the Victoria is disease-proof with him, but it is the Victoria that is giving trouble in Mississippi, although Schoenbrunn, Marie Louise, Swanley and a number of other varieties are perfectly healthy.

As the botanical department of this institution is giving attention to certain floricultural problems, among others the diseases of flowering plants, it would be esteemed a special favor if any of the readers of GARDEN AND FOREST having diseased Violets would send them to us by express after September 1st, for investigation here. It will be well to dig a little of the soil around the roots, and send them in as nearly the natural condition as possible. We propose to pursue a systematic study of this malady.

Agricultural Experiment Station, Lafayette, Ind.

C. S. Plumb.

Plants at Dongan Hills.

To the Editor of GARDEN AND FOREST:

Sir,—Since my last visit to Farview, Mr. Wm. Tricker has enlarged and increased his water-tanks, and has several noticeable ones, in which the lover of aquatic plants will find many objects of interest. A large tank of *Nelumbiums*, consisting of young plants of *N. speciosum* and *N. nucifera*, was interesting as showing the difference in growth of the two under the same conditions, the former variety being much more free in flower. These flowers in Japan are said to embrace a wide range of color, and it is to be hoped that among the varieties some may be found which flower more freely than any we yet possess. In another tank was a large selection of the leading varieties of *Nymphæas* grown for seed, and in many cases they had been carefully hybridized. Evidently we shall soon have *Nymphæa* hybrids to meet all demands for these favorite flowers. In this tank, for convenience, the crowns of the plants were placed just under the surface of the water, and the thriftiness of growth gave striking proof of the value of shallow culture. Mr. Tricker had in flower all the *Nymphæas* which have been mentioned in your columns, and I also noted in addition *N. elegans*, a beautiful variety of a medium size, with light blue flowers, apparently borne very freely. Seedlings of *N. Zanzibarensis* had numerous shadings of the typical blue or purple and some very charming forms with roseate hues. *N. Laydekeri*, the new *Nymphæa*, seems to be a wonderful variety in its strange range of colorings. Open on the same plant, at the same time, were flowers, nearly white, faint pink, deep pink and dark rose. Unlike most *Nymphæas*, the flowers seem to deepen in color as they grow old.

At one side Mr. Tricker was making a plantation of ornamental grasses, *Arundos*, *Eulalias*, etc. Among these *Eulalia gracillima univittata* stands first for grace, though many others are of nobler proportions. The Abyssinian grass (*Pennisetum longistylum*) made a striking show with its fluffy heads of bloom. Though an annual, it is one of the most valuable and effective of ornamental grasses of moderate height.

When the American florists make up their minds that certain plants are "good things," they cultivate those plants with great unanimity. They have certainly discovered the value and beauty of Crozy's Cannas, and here, as at most important places, was found a selection in a comprehensive variety. I did not note the names of the best kinds, but among them all Madame Crozy seems to be without a peer for finished elegance. The *Chrysanthemum*, evidently, is becoming a greenhouse-plant, and it must be said that here, as well as at other places, I found the plants under glass rather better than out-of-doors. The competition at the shows is now so close that the growers can no longer afford to take the chances incident to out-of-door cultivation. Nevertheless, the finished products seen in the shows, albeit more pure in color, seem to be lacking in the solidity of bloom found in those grown under more rigorous conditions.

Farview also possesses a private range of glass houses and extensive grounds which are under the able superintendence of Mr. Tricker. Among some elaborate bedding arrangements there was being tried a variety of *Sanchezia nobilis*, a very bright and effective plant. A good crop of peaches in one of the houses came from Hall's Early, which seems a finely colored decorative variety for dessert, but not high-flavored. A lot of Fig-trees were well set with fruit, and the cultivation here seemed a success, as did also that of Grapes—a small house of Sweetwaters and Black Hamburg showing a heavy crop of well-formed and well-colored bunches. In the plant-houses great use is made of *Allamanda Hendersoni*, one vine of which covered many square feet of glass and bore hundreds of beautiful yellow flowers. The scarlet Passion-flower seemed to be another favorite seasonable vine. A lot of the new seedling hybrid *Streptocarpus* were just coming into bloom, and seemed to be interesting plants in leaf and flower. They flower profusely, but one would hesitate to call them handsome, for they lack both the delicacy and the purity of color of other Gesneraceæ. Judging from these seedlings they need careful selection, many of them having blotches and markings of a dull purple, which could only be enjoyed by the color-blind. As they were grown in close proximity to a fine collection of Tydeas, Achimenes and Gloxinias their characteristics were unpleasantly accented. The houses also contain a fine selection of Orchids and foliage-plants, gems among which one inclines to linger, but the description of which is not likely to be of interest. Among the minor features of some of the houses beautifully developed by Mr. Tricker is the decoration under the benches, which is seldom seen so well carried out. Among a groundwork of low-growing trailing plants with variegated foliage were many clumps of fancy leaved *Begonias*, *Marantas*, *Alocasias*, etc., with grasses, while the variegated *Pothos* covered the posts with its close leaves. Such a feature as this is worth imitating in many other houses, where such spaces are often unsightly and detract very much from the appearance of handsome collections.

Elizabeth, N. J.

G.

A Pretty Native Vine.

To the Editor of GARDEN AND FOREST:

Sir,—The idea is prevalent that all variegated foliage is the result of low vitality or of actual disease in the plant. This may be the rule, but a ramble through our south-western woods would prove it to be a rule to which there are many exceptions, for here may be found several species of native plants clothed with prettily marked or mottled leaves, which, nevertheless, are apparently perfectly healthy and vigorous. One of these, *Passiflora lutea*, a small, slender-growing vine, with rather broad, obtusely three-lobed leaves scattered alternately along its stem, bears yellowish green flowers, so small as to be quite inconspicuous, yet worth studying, because of their curious fringed crowns and filamentous processes. Its foliage is decidedly pretty, and the graceful vine, with its clinging tendrils, would, if it were a rare exotic instead of a common native, become a great favorite as a basket-plant. Transplanted from the woodland to the foot of the rockery, these vines adapt themselves admirably to their new position, their delicate growth never quite obscuring the rocks over which they climb, yet softening the angularity of the cold, hard stone by their graceful tracery of leaves and tendrils.

In their own habitat there is a marked difference in the leaf-coloring of different individuals of this species. Perhaps one-third of them have no variegation, the leaves being of a uniform dark green. As Gray, in his manual, makes no mention of any leaf-marking in this species, he probably considers the plain-leaved examples the normal type, but in this section of the country the majority show a more or less distinct variegation, ranging from the plants whose leaves show only a few faint dots or splashes of pale green or ash-gray, to specimens whose leaves are heavily marbled with varying shades of green. In a leaf before me, the groundwork is a deep, even green, blocked with gray-green, light green and pale yellow. This leaf was taken from one of the plants at the rockery, where the soil is rich, and there is an exposure to the sun for a part of each day. They seem to deepen in variegation as they grow older and stronger, though this may be the result of a favorable situation. It is a little strange that none of our wild-flower dealers make mention of this Passion-flower, for it has certainly more merit than some upon their lists, and its range is enormous, extending from southern Pennsylvania to Florida, and west to Missouri and Louisiana.

Pineville, Mo.

Lora S. La Mance.

The Way-side Flowers.

To the Editor of GARDEN AND FOREST:

Sir,—I wish to make a plea for the preservation of way-side flowers. In the state of Connecticut, where wild blooms are in such profusion, the eye is delighted to see on every road-side the beauty of shrubs and vines. Each broken bank, with its adjacent rocks, makes a study for the artist, the pretty green and flowering things offering a picturesque foreground to every landscape. The sweet white Honeysuckle perfumes the air, and Wild Roses in great variety smile on the dusty traveler. The yellow Daisy opens its brown eyes to chide the tardy Golden-rod; the red Lilies flame in the fence-corner, yellow and pink and purple Heather have a home here among the Spiræa, the Cowslip and other natives of the soil. The Pond-lily opens its white disk on the waters, and in wet places the Marsh Mallow shows its spreading cups of delicate pink. The variety is endless, and the generous abundance of nature invites us to accept her gifts, though she does not intend they shall be taken with selfish waste.

But it is not only of these that I wish to speak. There are way-side flowers that, wandering from the garden, are flourishing in sunny spots outside. A group of Coreopsis, a Hollyhock, a plantation of Bluebells or Nasturtium often seek to root themselves or to send their winged seeds into the waste places, and become denizens of the soil. There seems an inherent desire on the part of every traveler to gather these way-side wanderers from the garden. Their rarity attracts the eye; the unexpected association with home-joys awakens the desire of possession, and so every bright flower, which, if left to ripen and scatter its seeds, might gladden the hearts of many in coming years, is quickly plucked from the stem, and after a moment of admiration carelessly thrown aside to make way for some new claimant upon the traveler's attention.

The beauty of the road-side is the property of all who pass, and no one has a right to destroy it. Indeed, the highest sense of obligation should impel each one to do everything in his power for the growth of flower and fruit, for the destruction of insect marauders or poisonous plants, but most of all should he leave untouched the fragile wild things that know so well how to take care of themselves when unmolested. And a deeper chord of human fellowship is struck when one reflects that for the quiet homes along the country-roads this wild beauty is often the only poetry of life, and there are those in humble dwellings and amid poor surroundings who value it and regret its loss.

Recent Publications.

Le Potager d'un Curieux. By Messieurs Paillieux and D. Bois (second edition, Paris, 1892).

Variety is the great characteristic of man's diet, as it is of man's raiment. Still, to confine our remarks to such articles of food as are derived from the vegetable kingdom only, it is curious to note that the number of fruits and vegetables usually found in the best-stocked market is a mere trifle in comparison with the total produce which might be used as food. Some nations have a much more extensive diet than we have, and a highly competent authority asserts that "one would sooner make a list of vegetable produce left uneaten by Chinamen than enumerate all the articles which they actually eat."

It should not be inferred, however, that no vegetable is worth growing and eating which is not as yet recognized as such in the civilized world. Some plants may want only to be better known or to have some time and care bestowed on their improvement to assume their rightful place in our gardens.

It is to these "unknown, or imperfectly known, vegetables" that Messieurs Paillieux and D. Bois have devoted for the last twenty years a good deal of time and study, collecting, in fact, information sufficient to make up a volume of nearly 600 pages, and of very great interest to botanist, gardener and amateur alike.

The number of vegetables alluded to in this, the second edition of the work, amounts to two hundred. All, of course, are not equally new or equally promising. Some, in fact, may be said to have been known for ages, and to be vanishing away from gardens rather than deserving to be introduced into cultivation. Such are among others: Skirret (*Sium Sisarum*), which seems to be losing ground every year; Cuba Purslane (*Claytonia perfoliata*), the Ice-plant (*Mesembryanthemum crystallinum*), and the Algerian Valerian (*Fedia Cornu-copizæ*).

A good many, again, are plants well known and even largely grown for some other purpose, either economic or or-

namental, which may be used as vegetables on an emergency, but of which no one would think as vegetables only. In this class we may include *Aponogeton distachyon*, *Camassia esculenta* (the Quamash of the western territories of North America), *Amorphophallus Rivieri*, *Lilium auratum*, *L. speciosum* and *L. tigrinum* of Japan, *Momordica Charantia*, *Nelumbium speciosum* (the Lotus of Egypt and India), *Oxalis Deppei*, and *Portulaca grandiflora*, which are very beautiful ornamental plants, but all of them very poor vegetables indeed.

Among the most promising of the plants introduced in the *Potager d'un Curieux* three are especially worthy of notice, namely, *Arctium Lappa*, var. *Japonicum*, *Soja hispida* and *Stachys affinis*.

Arctium Lappa, var. *Japonicum*, described also as *Lappa major*, is simply a variety of the cosmopolitan "Burr." The fleshy root of the plant grows and swells rapidly in deeply trenched soil; so much so that it can be obtained one inch thick in the space of three months, and yields a vegetable resembling salsify or scorzonera, but of quicker growth, very white and tender, and easily made very palatable by proper cooking.

Soja hispida is a Chinese plant of the order Leguminosæ, which is remarkable for the large proportion of fat and of nitrogenous matter contained in its seeds. It is from the *Soja* that the Chinese and Japanese manufacture the "vegetable cheese," a highly nutritious paste which can hardly be recognized from cheese made of milk, and the "Shoyou," a condiment of every-day use, which appears to enter largely in the composition of many of the patent "sauces" made in England.

Soja is not very delicate as a fresh vegetable, as the seed, which is the eatable part of the plant, has a very thick and hard skin. But it might be removed before dishing up. The plant is so prolific, so perfectly hardy and disease-resisting, that it would be worth while to devote some time and care to its improvement. Most varieties of the *Soja* ripen their seeds too late to be of much use in northern Europe, but several of them might be grown easily in North America.

Stachys affinis, otherwise *S. tuberifera*, first introduced to notice by Monsieur Paillieux, can be said to have attained in Europe the position of a standing vegetable. In France it is fast becoming popular as *Stachys*, or "Crosnes du Japon," and it is recognized in England as the "Chinese Artichoke." It is a perfectly hardy vegetable, consisting of the fleshy, pearl-white, underground stems of *S. affinis*. The tubers, although very watery to all appearance and easily crushed between the thumb and fingers, contain a rather high proportion of albuminous and gummy substances, and therefore constitute a not altogether despicable food. The tubers intended for propagation should be kept in sand over winter, planted out in rows or on mounds early in spring and left to themselves, with the exception of occasional weeding all through the season. The tubers are not wholly formed till the vines die off. They will stand any amount of frost if left in the ground, and they are all the more delicate for being pulled up just before cooking.

A good deal of attention is paid by the authors to such plants, or parts of plants, as are well adapted for being pickled in vinegar, so as to introduce some variety in the "pickles," too commonly made exclusively of gherkins, small onions and bits of cauliflower. The West India Gherkin (*Cucumis Anguria*), the tuberous *Nasturtium* (*Tropæolum tuberosum*), the *Martynia*, the Chinese Artichoke, and last, not least, the *Mioga*, the unexpanded flower of a sort of Ginger (*Amomum Mioga*), are specially recommended for pickling.

Many interesting points in this book are necessarily left untouched here, but enough has been said to show that it is a very curious work, stored with quaint facts and suggestive information. It contains the results of many years of careful study and of protracted experiment, and all references to other books or periodicals are most accurately given, by which the utility of the whole is doubled. The authors, too, have done their work in an evidently enthusiastic but entirely disinterested spirit, and in perfect good faith, plainly stating the pro and con in every case. This in itself is no small merit.

Notes.

The beautiful Royal Gardens at Laeken, near Brussels, with their magnificent conservatories, are frequently thrown open freely to the public, and recently 26,460 persons visited them during a single day.

Seven acres of Apricot-orchard in Tulare County, bringing their owner a return of \$2,100, and eight acres of Prune-orchard in San Bernardino County, yielding twenty-five tons of fruit,

which brought \$50 a ton, or more than \$150 per acre, are mentioned in this year's early reports upon the California fruit-crop.

The *Tombstone Epitaph* recently spoke of a garden near Yuma, Arizona, in which are growing twenty-five Date-palms, the largest of which is thirty feet in height and fifteen years old. This and five of the other trees are now in bearing, and some of the bunches of their fruit weigh fifty pounds, and are estimated to contain three thousand dates each.

Much attention was attracted among the visiting florists at the recent convention in Washington, District of Columbia, by the fine specimens of Crape Myrtle (*Lagerstrœmia*) to be seen in that vicinity. Chief among these was a magnificent plant in the old garden at Mount Vernon, the specimen in question being eighteen feet high, as many in diameter, and covered with large trusses of its lovely pink blossoms.

A correspondent of the *Journal of Horticulture* complains that *Salvia patens* is not met with as frequently as it once was. This seems to be true for this country also, and yet in late summer and early autumn we know of no plant whose flowers are of so pure and true a blue. It does not produce flowers so abundantly as does the Scarlet Sage, but it is quite as striking in its way among blue flowers as is *Salvia splendens* among scarlet ones.

At the recent meeting of the American Association for the Advancement of Science, in Rochester, it was resolved, in accordance with the advice of the Committee on Forestry, that such legislation as is contemplated by the bill introduced and reported by Senator Paddock (S. 3,235), which provides for the preservation and practical administration of the public timber domain, deserves commendation; and it was resolved further, that copies of the resolution be sent to the President, the presiding officer of the Senate, and the Speaker of the House of Representatives.

Over 250,000 pounds of beet-sugar have been produced at the Chino factory, in San Bernardino, California, from this year's crop, showing an enormous growth of this industry in the state. Four hundred thousand acres of Beets were planted against 2,700 acres last year. The growers have netted \$4.50 a ton, and one man, who bought twenty acres of land and raised fifteen tons to the acre, paid for this land with the first beet-crop. Since a bounty was placed on beet-sugar, the farmers of California have been quick to see the profit in this industry.

Two very fine pans of the Brazilian *Hippeastrum reticulatum* are in bloom in the greenhouse of H. H. Hunnewell. There are twenty scapes in one and seventeen in the other, averaging five flowers to a scape. This species is nearly evergreen, and is handsome even when out of bloom. The leaves are a very dark green, sharply recurving, with a white stripe down the centre of each leaf. The flowers are borne on stout scapes a foot or more high, about four inches in diameter; segments, unequal, spreading and recurving; color, soft pink, with a deeper-colored reticulation running through the flower, from whence comes its specific name.

The *Horticulteur châlonnais*, for the benefit of those who may desire to preserve blossoming flowers fresh for several days, says that this end may be obtained by snipping off the tops of their pistils and thus preventing fructification, which hastens the withering of the flower. But it likewise gives a less well-known receipt, which is, that a small incision made in the pedicel of the flower, or near by in the branchlet which bears it, causing the flower to bend a little to one side, will retard development by partially stopping the flow of sap. If this operation is performed just before a bud unfolds, it will open much more slowly and yet lose nothing of its beauty or perfume.

From a recent bulletin from the Florida Experiment Station it seems that while the weight of an orange steadily decreases after it is picked, the specific gravity increases for a while and then falls off—that is, for a period after plucking, the orange becomes more and more compact and afterward it “loosens up,” so to speak. The specific gravity of a freshly pulled orange is generally less than unity. It increases for a while, as the drying goes on, and then decreases, the maximum often exceeding unity—that is, an orange which at first would rise in water will after a few days or a week sink and afterward rise again. In making up the scale for honors and medals, weight counts ten points. In view of this fact, it would be manifestly unfair to compare the weights of oranges that have been pulled from trees different lengths of time.

The practice of enclosing grape-clusters and other fruits in bags of paper or of thin woven tissue as a protection against insects and fungi is perhaps more common in some parts of Europe than it is in this country. A contributor to a Belgian horticultural journal recommends, as particularly well adapted for this service, bags of transparent oiled paper such as is used by draughtsmen for making tracings. “The transparency of this paper,” he says, “permits the fruits to profit by solar light and heat. Grapes, Peaches and Apricots trained on espaliers in the open air find in them something of the atmosphere of the hot-house. Inside a hot-house they are equally useful, for, being impermeable, they permit that spraying of the vines or trees with insecticides which is now usually abandoned as the fruit begins to develop. And the bloom of fruits grown in these receptacles is exquisitely preserved.”

In a recent bulletin from the Cornell Experiment Station on the comparative merits of steam and hot water for greenhouse heating, it is stated that a comparative test conducted there led to the conclusion that under the conditions at the station steam was more economical than hot water, and more satisfactory in every way. While not condemning hot water, Professor Bailey, under whose charge the experiment was made, adds that, in his belief, steam is superior for very large houses where the fall is slight, for most forcing-houses and for all establishments which are likely to be often modified and extended. Steam overcomes obstacles such as elbows, angles and obstructions better than hot water, and it travels faster and farther. It can be varied more quickly than hot water, and yet under proper management it is quite as steady, and requires no more attention. For conservatory purposes, for straight runs and small houses steam is equaled, and possibly, in some instances, surpassed by hot water. In forcing establishments where hot water is used it is most satisfactory when conducted in wrought-iron or gas pipes in essentially the same manner as steam.

Many persons have been enquiring of late why there has been so much delay with regard to the establishment of those small parks in the poorer districts of New York which were provided for by a law passed in 1887. Perhaps there has in some cases been more delay than was absolutely needful; but few people realize how slow are the processes by which city property, in the hands of a great number of owners, can be transferred by condemnation proceedings to the guardianship of the city. The sites for several new small parks were long ago decided upon, and the Commissioners of Estimate and Apportionment have been busily at work in the matter, but have not yet brought it to a conclusion. These proposed pleasure-grounds include Mulberry Bend Park, to create which the notorious crooked street of rookeries will be swept away; a park near St. John's Church; and Corlear's Hook Park, near the East River. But even sooner than for these we may look for Rutgers Park, at Rutgers Slip, and the extension of East River Park. The land in these two cases already belongs to the city; plans for both parks have been considered by the Park Commissioners; \$23,000 has recently been appropriated for Rutgers Park, and the work there as well as at East River Park will be begun as soon as the contractors can get to work.

In the Boston *Transcript* the Listener describes a garden which is full of interest as showing how a love of growing things and care for their welfare can find expression in the most sordid surroundings. This little garden, not more than fifteen feet in length by twelve in width, is to be found in Boston in a half-slum street largely inhabited by colored people. It contains in one corner a large Mock Orange, and in the opposite corner another similar shrub. Along one side of the area are many plants of Violets and Lilies-of-the-valley, all in a thrifty condition, while pretty bunches of Oxalis in bloom nestle in all the corners. Along the other side of the area is a row of tall Ascension Lilies, now out of bloom, of course, but telling a story of past magnificence. Massed together in the centre are many fine potted plants in flower. All the space is utilized, and there are several plants and creeping vines whose names the Listener did not know. To crown all, a splendid specimen of *Ampelopsis Veitchii* ascends the house-wall, spreading right and left over the long brick block, and covering the fronts of the adjoining houses, where it has intertwined itself within the slats of the shutters so that they can never more be closed. It is in such service as this that the luxuriant climber which the Japanese have lent us finds its perfect work, covering and cooling the hot walls of humble dwellings and bringing something of color and brightness into the dull monotonous lives of the toiling poor.

The Boston Metropolitan Park Commission.

THE Metropolitan Park Commission, which has lately been organized for the area known as Greater Boston, marks an important step in the progress of the park movement in the great cities of this country. The Commission is one of investigation, appointed by the Governor, to inquire into the needs of the cities and towns in the vicinity of Boston, and to report to the Legislature in 1893 a plan for the provision of ample open spaces in the territory under consideration. The limits of the territory are not defined, and the scope of the investigations in this respect, as in others, is left to the discretion of the commissioners. The establishment of this Commission is an outcome of the organization of the Trustees of Public Reservations, and a direct result of the conference of Park Commissioners and others interested in the subject called by the Trustees last autumn, and held at the office of the Boston Park Commission, an account of which was given in GARDEN AND FOREST (vol. v., page 62). That such a commission has already been authorized is a sufficient indication of the rapid growth of public sentiment in favor of public recreation-grounds. Fortunately, the members of this Commission are admirably qualified for their work. They are all well known, not only as men of broad public spirit, but they have been generously and intelligently active in many worthy projects for establishing and maintaining public parks and for preserving for public use places which have a special value from patriotic association or intrinsic beauty.

It is probable that the scope of the inquiry undertaken by this Commission will be sufficiently broad and thorough to enable the city to deal intelligently with all the important park problems which now confront it. Among the features of the investigation ought to be the reservation of large woodland and hilly areas like the Middlesex Fells and the Blue Hills; of points of marked picturesque, historic or traditional interest like the "Appleton Pulpit,"

in Saugus, with its neighboring lake-scenery, and the Waverley Oaks in Waltham; of the various lakes or ponds in the metropolitan region; of the margins of the rivers and streams, including the beautiful expanses of salt-marsh bordering their tidal estuaries; of spaces by the sea-shore sufficient to permit water-side recreation; of the reforestation of the islands in Boston harbor; and, finally, a study should be made of the important question of sufficient playground and breathing-spaces throughout all the territory in the suburbs of the city.

A population of something like a million inhabitants is included within the territory which will probably be covered by the investigations of the Commission. There are many passages of strikingly beautiful scenery within this area, but the population is increasing so rapidly that every year sees lamentable encroachments upon some of the most charming landscape passages. There is now an opportunity to deal comprehensively with the subject, and to secure the permanent reservation of precious natural features which many another city with a liberal and far-seeing policy in regard to park matters would have regarded as of priceless value had they existed in its neighborhood. Indeed, Chicago has gone to the trouble of creating, at great cost, landscape-effects which at best are quite inferior to many a scene already existing in the neighborhood of Boston and only need to be preserved.

Fortunately, the public mind is becoming alive to the importance of definite action in the near future, and if the Commission reports a plan covering the ground most thoroughly it looks as if the power of popular sentiment might effect its adoption. Already in a considerable number of the separate communities interested steps have lately been taken looking toward the acquisition and improvement of public grounds, and local park commissions have been appointed. But small communities are apt to deal with such matters solely in relation to their own locality; and they can hardly be expected to treat them as parts of some general system, especially if no such system has been planned. Besides, in places growing as rapidly as the Boston suburbs are growing, there are always matters demanding immediate attention and large outlays, such as sewers and sidewalks to construct, roads to improve, school-houses to build, water-works to extend, and these take precedence of works of an "ornamental" character, as parks and playgrounds are too apt to be regarded. Where park improvements have been taken in hand in these places the methods employed and the results achieved have usually presented an unfavorable contrast to the comprehensive way in which the great central municipality has dealt with the subject, both artistically and practically. It therefore seems desirable that the entire metropolitan region should be treated as a unit in the planning of a system of parks and other open spaces.

Altogether, the formation of this Commission seems to us an event of more than local significance. There are many American cities which are expanding as rapidly as Boston is, and which are in immediate need of provision for future parks. The report of this Commission ought to be an important contribution to the literature of the subject, and it will have a special value if it carefully considers the machinery and methods of administering a system of city parks after they are once established.

In his article, entitled "The Tilden Trust Library: What shall it be?" published in *Scribner's Magazine* for September, Mr. John Bigelow declares that, as regards this question, "the press of New York has a manifest duty, for it is only through the press that the best judgment of her citizens can be evolved, and the public authorities properly encouraged and sustained in giving that judgment fit and adequate support." In the performance of this duty we feel impelled to say that our views differ from those of Mr. Bigelow as regards the proper location for this library.

Mr. Bigelow believes that, if the reservoir on Fifth Avenue can be dispensed with, the library should be erected on the open site which will then embrace the whole area bounded by Fifth and Sixth avenues and by Fortieth and Forty-second streets, and called Bryant Park. The pictures which accompany his article give a pleasing idea of the aspect this square would present with a large library in the centre and four small gardens in the corners, which the cruciform plan of the proposed building would leave vacant. And he is quite right when he says that the situation is so central, and access to it so convenient, that "no site better adapted for a structure of suitable proportions for a metropolitan library could be carved out of any part of the city than this of Bryant Park." But the suitability of the site for a worthy purpose is not the only thing to be considered. We must weigh what we should gain against what we should lose. A single spacious park covering all this site might be of greater advantage to the city than a library and four little parks, and no one needs to be told that playgrounds for children and breathing-places for adults are of the first importance to the well-being of a large city; or that New York, below Fifty-ninth Street, is deplorably poor in such open spaces.

Mr. Bigelow is careful to point out that, if the library is planned according to the pictures he shows, the four gardens for which it will leave room will be larger, in the aggregate, than the space now actually occupied by Bryant Park, as the reservoir now covers a little more than one-half of the area that is called by this name. But four little isolated gardens, each enclosed on two sides by the walls of the library, would be of much less value than a single wide open space almost equal to them in extent. Fresh air, free winds, an open outlook, long vistas beneath umbrageous trees, considerable lawns where the eye can find refreshment, and extended walks where children can play—these are now to be had in Bryant Park; and a visit to it on any pleasant afternoon will prove how thankfully its opportunities are enjoyed by hundreds of poor people from the teeming streets which lie to the westward. Can any one think that their needs would be as well served by four gardens, each about one-fourth the size of this park? Furthermore, it takes a generation for trees to grow to the size now attained by those in Bryant Park. Most of these would perish were the library built, and the present generation of children would be grown up before the corner gardens could assume a shady beauty.

But the question is not between the four proposed gardens and Bryant Park, but between the four gardens and Bryant Park as it might be with the reservoir removed. If this were ever taken down and the vacated area added to the space already open there can be no doubt of its paramount value for park purposes. There is no other space of such a size available between Madison Square and Central Park, and to condemn it to any other purpose would be to deprive New York of its only opportunity to meet a most urgent necessity. The city is not forced to decide between the loss of the library and the loss of the park, but between the loss of the park and the erection of the library somewhere else, which might not be a serious calamity. Bryant Park is a good site geographically now, but twenty years from now it will probably be too far down town. And even if the library were driven to some less attractive and accessible place, the people of the city could endure that with less regret than they would feel for the sacrifice of another considerable fraction of the scanty park area of the city. It has taken years of earnest labor by many public-spirited citizens to organize a public sentiment in favor of the sacredness of every foot of open space on Manhattan Island. There is reason to believe that the people have become determined to allow no disfigurement or curtailment of their parks, and to tolerate no scheme which diverts them from their primary purpose. It is to be hoped that this sentiment is sufficiently strong to defeat such a precedent as would be established by the covering up of Bryant Park with a public building.

The Botanical Garden of Dublin.

AT this time, when there is so much discussion of the establishment of a Botanical Garden in New York City, an account of the Botanical Garden of Dublin may prove of interest. From an article in a recent number of the *Gardeners' Chronicle*, written on the occasion of the tercentenary celebrations of the University of Dublin, it appears that the present Botanical Garden of Trinity College is to be the third of its kind attached to the University. As early as 1710 there seems to have been a Physic Garden which occupied the site of the present library, or, according to some traditions, that portion of the present Fellows' Garden which lies between the library and the Nassau Street boundary. Between 1791 and 1801 several attempts to establish a botanical garden which should be common to the University, the College of Physicians and the Dublin Society proved unsuccessful. But, in the mean time, Dr. Hill, the professor of botany, had rented some ground at Harold's Cross for the purpose of a botanic garden, and he was assisted to some extent by the college. In 1801 a curator was appointed, but it is clear from the college accounts that the plants and houses were to a very large extent, if not altogether, the private property of Dr. Hill, and we also learn from the same source that he was the means of securing for the Dublin garden, through Sir Joseph Banks, many of the plants and seeds brought to England from the South Seas by the members of the exploring expeditions of the time. The article goes on to say:

In July, 1806, the site of the present Botanical Garden at Ball's Bridge was leased by the college for one hundred and seventy-five years at a rent of fifteen guineas per acre. The present garden was commenced in the autumn of 1807, and consisted of about three acres of ground as represented to-day by the botanical portion proper—namely, that situated within the old walls—and the oldest and largest of the trees in this enclosure were mostly planted in the spring of 1808; so that the fine and graceful American Elm, the tallest tree in the garden, the Copper Beech, the characteristic Cedar of Lebanon, and the Italian Stone Pine, the Manna, or flowering Ash, the weeping Elm beside the pond, and other less notable trees have all grown to their present dimensions in a little over eighty years.

In 1832 an addition of about two acres was made adjoining the Blackrock Road, now Pembroke Road, so that the finest of the specimen Hollies, the weeping Beech, Pinus, Platanus, Oak, Arbutus and Garrya here to be seen are only about sixty years old at the most, and show what has proved possible in a town garden in so short a time.

The latest addition to the garden was made in 1848 by the further enclosure of about three acres, or less, which now adjoins the Lansdowne Road, this having been taken in "with a view to admit of a screen being planted parallel to the older north-west wall, and thus afford sufficient protection against smoke, buildings, etc." The last extract from a report prepared by the first curator and designer of the garden, the late James Townsend Mackay, LL.D., illustrates his ability and far-seeing knowledge as a landscape-gardener, for on these two additions, and the exquisite fitness of their fringe of Ilex or evergreen Oaks and Hollies, depends whatever is verdant and beautiful, and sheltered in the garden at the present time.

Mr. John Bain, A. L. S., who was assistant-curator in Mackay's time, afterward succeeded him as curator, and the gardens were much improved under his care. Altogether, Mr. Bain was over forty years employed in the garden. His keenness as a botanist, especially his critical knowledge of native plants, and his remarkable skill as a cultivator, were recognized by the most noted botanists of the time, such as Professor Allman, Dr. William Harvey, Sir W. Hooker, the late Mr. Jas. Veitch, Rev. Wm. Ellis, and Archbishop Whately, who for many years was a constant visitor to the gardens. At this time many then rare plants were grown here with a success perhaps never surpassed. Of such were *Vanda cœrulea*, the true old *Cattleya labiata* and *C. violacea Harrisoni*, *Renanthera coccinea*, *Zygopetalum Mackayi*, *Mackaya bella* (a shrubby Cape Acanthad, founded by Harvey in compliment to Mackay, since called *Asystasia* by Hooker and Bentham in *Gen. Plan.*), *Erica Mackayana*, *Saxifraga elegans*, etc., were also introduced to public notice by Mackay. Here also Mr. W. Ellis and Sir W. Hooker alike saw *Ouvirandra fenestralis*, *Dionæa Muscipula*, *Cephalotus follicularis*, and the North American *Sarra-*

cenias, in luxuriant health and beauty; and the Cape Disa grandiflora bore flowers as large, and as fine in color, as Harvey had seen them on Table Mountain only a year or two before. Mr. F. W. Moore, now of Glasnevin, also had charge of the gardens, and by his zeal and well-directed industry contributed to their present prosperous condition.

Without undue boasting, it may fairly claim to be, in proportion to its size and general conveniences, a garden as rich in vegetation of all kinds as exists elsewhere in Europe. The main drawback is its proximity to dusty roads and to the smoke of the town. Its best features are excellent shelter—for reasons before expressed, a remarkably deep alluvial soil overlying a gravelly subsoil resting on chalk limestone, abundant moisture, and a climate much to be envied by those of more northern latitudes or farther from the sea.

Many plants, only half-hardy elsewhere, even in the same latitude, here exist perfectly in the open air. Especially noticeable in the garden are the walls which, while giving shelter from the prevailing winds, also serve in the conservation of the rarer of half-hardy shrubs, such as the Loquat, Carob Bean, *Mutisia decurrens* and the Chilian *Colletias*; Australian Blue Gums, or Eucalypti; the Japanese Wineberry (*Rubus phœnicolasius*), "Winter's Bark" (*Drimys Winteri*) from Magellan, and *Wistaria* from Japan; *Clematis alpina*, a sort of shrubby Anemone, from Austria; *Veronica Hulkeana* from New Zealand and *Berberidopsis corollina* from high up on the Chilian Andes. *Choisya ternata*, *Smilax latifolia*, *Zizyphus* (*Paliurus*) *spina-Christi*, *Solanum crispum* and *Mahonia nepalensis* also do well here. Here and there also various interesting rock-plants from the limestone or chalk, the granite from basal Cambrian, or old red sandstone, are here grown in extemporized niches or "pockets" especially prepared for them. You may see the Pyrenean *Ramondias* so grown, also Edelweiss from the Swiss Alps, and *Androsaces*, such as *A. lanuginosa*, from the Himalayas. The last-named plant was first flowered in this garden by Dr. Mackay in 1842. *Dianthus*, *Linarias*, *Erinus* and *Iris* of many kinds are at home on these wall-tops, and quite recently a special hollow plant-wall has been erected for these and other denizens of the rocky places of the temperate world. A small pond fed by the Dodder River is rich in *Aponogeton* and *Nymphæas*, several of Monsieur Latour Marliac's hybrid kinds having passed through the last winter unscathed. The great *Gunnera manicata*, with leaves five to seven feet across, is here quite at home, as also are the red and green veined forms of *G. scabra*.

The strong points of the garden are its large herbaceous borders, now gay with many summer flowers. It is also pre-eminently a garden of hardy bulbous flowers of all sorts, Snowdrops, *Crocus*, *Narcissus*, *Tulips*, *Iris*, *Lilies* of many kinds; and to see the *Crocus* or the *Narcissi* at their best here, late in March or early in April, is a sight not readily to be forgotten.

Overland in the Cayuga Country.—II.

VERY beautiful is the neat and quiet road in this high country beyond Trumansburg. Visitors who now and then come from some western state remark the absence of weeds in the fields and along the road-sides of New York and New England. Yes, weedy road-sides are rare in this Cayuga country. The sides have long since grown soft and smooth under the lapse of time and the occasional plowing and grading. The grass has crept over them in a hard and continuous sod, and the farmers mow them as they do their meadows. Now and then clumps of wild bushes have sprung up at will on the corners or in the hollows, and so long as they do not interfere with the roadway they are not disturbed. Although they may not tell you so and may not even know it themselves, these people have grown to love the copses and wood-lots for their own sakes, for the labor of clearing has long ago been forgotten, and the passion to cut away every green thing has passed away. How well I remember my early days in the woods of Michigan! Cutting and clearing and burning! These were the three merits of the pioneer, and it is little wonder that he came to look upon every bush and tree as a personal enemy. There was no quarter; everything must be swept from the land—every bush on the road-side, every tree in the fields. And long after the farms had been cleared and the roads had become settled and worn this passion remained. But it is gradually burning out, and the next generation will have forgotten it and will look with satisfaction upon the clumps of trees and bushes that here and there spring up in the waste places. The pioneer, and too often the lumber-dealer, have no patience with any talk about forestry—this science must find its chief inspiration in the older states.

One thing more about these roads I must mention in passing: there is no rectangular road system in New York as there is in most of the newer states. It is a blessing that this is so, although there was a time when I looked upon section-lines and quarter-section-lines as the fundamental desideratum in road-building. But I no longer think of a hard-and-fast rectangular road-system with pleasure. The "angling" roads are commonly the most direct communication between neighboring villages, and if they follow the natural trend of the surface as much as possible, they are always beautiful and interesting. Rectangular roads would be the ruin of this fine country, for to toil over hills and ride straight across the hollows and never follow the creeks would be intolerable. Stretching out to the south-west from Trumansburg is an old and well-traveled road which winds along the valleys to Watkins, at the head of Seneca Lake. I have long told my students that a curved drive is attractive largely because it presents new views at every point, but I never caught the full meaning of my own teaching until I drove on this old turnpike. In many places the curves follow each other so rapidly that the traveler is constantly on the alert for new scenes, and these scenes are all the more forcible when they strike one suddenly. But when we came out upon a long straight portion of highway, the feeling was wholly changed. The prospect pleased at first, but it soon grew monotonous, and we fell into conversation.

For ten miles beyond Trumansburg there is little change in the aspect of the country. We still keep within occasional view of Cayuga Lake, and the hills are lower than they were a few miles back. Near Farmer Village we find the first unmistakable evidence of the new life which is brightening the farms of much of this lake region, for here we come upon the Grape. The Grape interest of western New York is very large and is rapidly growing. The census of 1890 showed that the largest vineyard area of native Grapes in America is the New York region, including a strip of Pennsylvania lying along Lake Erie. Some 51,000 acres were found to be devoted to vineyards in this region, and the product sold in 1890 as table grapes was 60,687 tons. The heaviest Grape regions in New York may be said to be four, those lying about Seneca and Keuka Lakes, in Chautauqua County, facing Lake Erie, and along the Hudson. The Seneca Lake district, which is noted for its Catawba vineyards, is now extending itself eastward in this central and northern part of the divide toward Cayuga, and it has even now reached this lake. Most of the Seneca Grape district lies upon the west side of that lake and well toward its southern end, but its eastern branch is now making this broad expansion, the borders of which we have reached at Farmer Village. The particular interest at this brisk hamlet in a horticultural way centres in the Moore's Diamond White Grape, which is here planted more largely than elsewhere. One hundred acres of this variety were set in a solid block in 1891, and this spring fifty additional acres were planted alongside. The hundred-acre plot is now planted to posts, and at a distance it reminds one strongly of old burned tracts in the Pine plains of Michigan, every bleaching-post suggesting the stub of a tree. In all this great tract the ground is kept scrupulously clean. It will be a test vineyard of this new variety of Grape, and it will be watched with eager interest by every grape-grower in the north. There are few White Grapes which can assume to be market varieties, and there is yet much doubt among the more conservative growers whether a white grape will ever find an extensive sale. It is understood, however, that the Diamond is to be a competitor of the Niagara. It certainly has the merit of better quality, but its virtues in the vineyard and on the road are yet largely to be determined. It requires many years to learn the true merit of any Grape, or of any other fruit, for that matter. The value must be largely determined by the uniformity of its behavior during a series of years. And yet nurserymen and others ask the experiment stations for a report upon their fruits the very year following the planting.

Although this is a large vineyard, we shall find much larger ones. This, like most of these very large vineyards set to a single variety, belongs to a stock company. This concern is known as the Boyer Diamond Vineyard Company. Like all large enterprises, it is having a stimulating effect upon the community, and private vineyards are now springing. These new great vineyards are introducing many new problems into the grape business of western New York, particularly as regards hand-labor, which must be reduced to a minimum. The first revolution which it is bound to introduce is in methods of training. The training in common use on Seneca and Keuka lakes is a species of renewal, by which the wood is renewed each year back to the crown on the lowest wire. A cane is trained out in each direction from the head on the lowest wire,

and the shoots are tied to the wires above as they grow. This summer tying is expensive, and the new vineyards are therefore mostly adopting the Kniffen system. This system uses but two wires, while the other uses three, and the canes are trained out on both wires in opposite directions, and the shoots are allowed to hang, thus avoiding summer tying. This system is now the common one on the Hudson, and it is much used in Chautauqua. It has many merits for strong-growing varieties such as Concord, Worden and Niagara, and on the Hudson I have seen even so slender a variety as Delaware doing well trained upon this system. This Boyer vineyard at Farmer Village will be trained upon the Kniffen system, and its behavior will be watched with interest.

Notes on the Flora of Smythe County, Virginia.—IV.

A MONTH and a day later, during the last week in June, we undertook a second trip to White Top. It was mid-summer in the Holston valleys, as far as temperature was concerned, and midsummer, too, in the world of vegetation, for flowers were few and nature was resting preparatory to putting on her autumn dress of Golden-rod and Aster, great quantities of which were just beginning to indicate their coming glory of gold and purple. For the first time we had fair weather on the Iron Mountain, and from the gap there were able to see the great sweep of the Alleghanies to the north and north-west. The steep summit of White Top was much more accessible than on our former visit, as the United States Coast Survey had, a few days previous to our arrival, ruthlessly cut long sights in two or three directions through the tall Spruces on the top of the ridge.

Since our first trip the Laurel (*Kalmia latifolia*) had bloomed and passed away, and the great ravine beyond the Iron Mountain was given over to Hemlocks, *Rhododendron maximum* and *Mitchella repens*. The *Rhododendron* was in bloom, and for miles we were surrounded by that stately shrub. At our feet the little Partridge-berry was at the height of its flowering season, and every inch of ground, even to the banks and cuttings along the road, was decorated with its long trailing vines, laden with the little fragrant flowers and many of the bright red berries of a former season.

In the deep woods, on the White Top slope, three Orchids were blooming. The little *Listera convallarioides*, a pretty inconspicuous greenish-flowered plant, grew mostly among mosses under coniferous trees, and in the same localities the handsome *Habenaria orbiculata* towered high above its humble relative. It is a beautiful plant, with two great round shining leaves spreading flat on the ground, and a slender, erect spike nearly two feet high, bearing large green and white flowers. The smallest of the three Purple Fringed Orchids, *H. psycodes*, was abundant all through the swamp and in the mountain rills, where it grew among the tall Bracken and other ferns. The great banks of *Diphyleia cymosa*, which had been in full flower a month earlier, were now in fruit, and *Trautvetteria palmata*, an exceedingly pretty white-flowered plant, bloomed in its stead, filling the woods for some distance on both sides of the road. Both *Picea alba* and *P. nigra*, both trees locally called Lash-horns, grew there, and we were told of the existence of two trees of *Abies Fraseri*, which, however, we were not fortunate enough to find.

The margins of the White Top field are bordered with what appears to be a series of old fruit-orchards. The majority of the trees were *Cratægus punctata*. The small leaf-buds only had been visible on our first trip; they had flowered in the interim, and the fruit was already half an inch long and very abundant. They were beautiful, crooked, wind-teased old trees, with flat, symmetrically spreading branches. With them were a few trees of *C. coccinea*, smaller and more shrub-like, though we did see one tree that was a foot in diameter. A few fine old Cherry-trees, *Amelanchier Canadensis*, two feet in diameter, *Pyrus Americana*, nearly as large, *Quercus rubra*, with Beeches and Birches, the two Spruces and an occasional Maple made up the majority of the trees along the summit, where on the topmost crags some very large *Menziesia globularis* was lingering, and the pretty *Vaccinium erythrocarpon* was flowering in great profusion. The common Wood Sorrel (*Oxalis Acetosella*) was there also, and we were very much interested in some of the little plants that had produced pink-purple flowers.

The luxuriant undergrowth of Ferns was in itself worth the journey. Along the edges of the field *Dicksonia pilosiuscula* had complete possession. Near the moss-hung cliffs there were great banks of *Aspidium spinulosum*, var. *dilatatum*, tall, magnificent specimens nearly three feet in height. In the Spruce-swamp and the woods below we found the va-

riety *Intermedium* of the same species, and growing with it *Asplenium thelypteroides*, *A. Filix-fœmina*, *Osmunda Claytoniana*, *O. cinnamomea*, the delicate light green *Aspidium Noveboracense*, *A. marginale*, and last, though by no means least as to size and beauty, the handsome dark green *A. Goldianum*. There was scarcely a flower to be seen, but, in their place, banks of feathery Fern-fronds of many shades of green. The finest forest that we saw during our many excursions into the highlands was the one on Pine Mountain, on the border of Grayson County, and the lowest of the three high peaks of the White Top range. If there is such a thing left in south-western Virginia as forest-primeval, it is to be found along Fox Creek, where for several miles we walked through the pathless tract of great trees. It was impossible for us to estimate the dimensions of the trees. The forest offered an apparently endless vista of massive branchless trunks that towered for a hundred feet or more above us into a great canopy of green, and many a prostrate giant proved too great an obstacle for weary feet to climb over.

The Sugar Maple, which is here the variety *Nigrum* is found in groves, and our young guide told astonishing stories of the large amount of sugar the trees produced. The Red Maple was there also as a large fine tree. The Black Walnuts' superb trunks, unique in size and beauty, were as yet undisturbed by the all-destroying lumberman. Chestnuts were beginning to bloom, and vied with the giant Tulip-trees in the straightness and breadth of their huge trunks. The Chestnut Oak, White Oak and Red Oak were also conspicuous members of the forest. Ashes were laden with fruit, and two Lindens (*Tilia Americana* and *T. heterophylla*) were beginning to open their little round flower-buds. *T. heterophylla* is one of the most showy of the deciduous trees of the mountain forest, its large, very dark green leaves, with the silvery under-surface standing out from the banks of lighter foliage in a particularly conspicuous way. The Beeches were covered with their little triangular nuts, and both *Magnolia Fraseri* and *M. acuminata* were also in fruit, the latter growing to a great size.

There was very little undergrowth, and flowers were few. On some of the boulders the great, smooth reddish canes of *Rubus Millspaughii* (a newly described species, first found in the mountains of West Virginia) grew over twelve feet long and were covered with broad white blossoms. *Clethra acuminata* was quite abundant in more open situations, and along the edges of the woods *Oxydendrum arboreum* was showing its white buds. So dense was the shade under the trees that the flaming *Rhododendron calendulaceum*, long past its flowering season in the open, was still in full bloom and reached nearly fifteen feet in height. Those who were intrepid enough to climb to the top of the mountain told tales of great Spruces over three feet in diameter. The forest is what is locally known as the Douglas tract belonging to some New York gentlemen, and it is to be hoped that it will not share the fate of the forests of the Doe River Gorge, that are being so rapidly exterminated.

One of the rarest of the mountain plants found that day was *Boykinia aconitifolia*, a pretty white-flowered species belonging to the Saxifrage family, growing on the stony edge of one of the little cold brooks with *Thalictrum clavatum*. Near it, on some tall cliffs, we found the nearly equally rare *Asplenium montanum*, not the plant with tiny fronds that grows in clefts of high mountain rocks, but a large beautiful plant with dark green fronds over six inches long, growing in spreading tufts along the crevices of the rocks.

New or Little-known Plants.

Smilax glauca.

AMONG our common and familiar plants are many which gardeners know little about, and their beauty and value from the garden point of view is not realized. A number of such plants have been figured in this journal from time to time, because we feel that in making them known we are doing a real service to the owners of gardens who, ignorant of the true resources of the American flora, bring less desirable plants than those they could find growing almost at their doors from the four corners of the earth to decorate their estates. Such an unappreciated plant is figured on page 425 of this issue; it is the glaucous-leaved *Smilax* (*Smilax glauca*), a common inhabitant of dry sandy uplands from eastern Massachusetts to Florida and Texas. Like nearly all the species of the large

genus to which it belongs, *Smilax glauca* is an extremely ornamental vine. It is a rampant grower, with long stout stems armed with scattered prickles, large pale leaves, small green flowers, and clusters of handsome black fruit covered with a pale bloom. Less vigorous and less ter-

The genus *Smilax*, as represented in the North American flora, is a considerable one, and many of the species are still very little known or understood, many of them having never been cultivated, although in order to thoroughly comprehend their peculiarities they must be brought to-

Fig. 70.—*Smilax glauca*.—See page 424.

ribly armed than the more northern Bull Bay or Green Bay (*Smilax rotundifolia*), it grows to a good size in rich soil and is a useful subject for the wild garden, to drape rocks, to help in the protection of boundary plantations, or to use wherever a handsome hardy free-growing vine with tough armed stems is needed.

gether into a garden. Not long ago one of the most ornamental of the North American species was figured in these columns (vol. v., p. 53), and we hope from time to time to bring others to the attention of our readers, that the lovers of hardy plants may learn of their existence and value as ornaments of the garden.

Entomological.

Notes on Two Troublesome Borers.

IF William Cobbett, that enthusiastic Englishman who so ardently praised our common Locust (*Robinia Pseudacacia*) and advised its general introduction into Britain and Europe a century ago, could have had a few years' experience with the borer which almost renders the successful cultivation of the tree in New England a hopeless task, he would probably have qualified his expressions of admiration and commendation. But the Locust is now a common tree all over Europe, in many parts of which there are trees of fine proportions, and all, apparently, unattended or unaffected in the least by our handsome brown and golden-yellow banded beetle (*Cyllene Robinia*) which does so much mischief as a borer in the early stages of his life. The insect has apparently not yet been introduced into Europe, and there seems to be no reason or probability that it should ever be taken there. The only danger lies in the importation of young infested trees or affected lumber. But, excepting perhaps some peculiar varieties or forms which may be sent out by her nurserymen, or some rare allied species, plants are now never imported, for the species has become almost like a weed in some parts of the Old World.

Besides affecting the common Locust, this borer is also very injurious to the Clammy Locust (*R. viscosa*), the Rose Acacia (*R. hispida*), and in the Arboretum it proved a serious foe in the successful cultivation of the newly introduced *R. Neomexicana* from New Mexico. In fact, it appears more partial to the last species than to either the Clammy Locust or the Rose Acacia.

We are more frequently asked about this pest than almost any other. Like most other borers, this is a very troublesome insect to combat. It is usually more destructive to trees in the open and sunlight than to those growing thickly together in groups or woods. The best, and, in fact, the only suggested remedies are preventive. To give the trunks and larger branches a thick and thorough coat of whitewash, with a large proportion of soap in it, is the best we can do; and where idle children abound it would be an excellent plan to have them daily collect all the showy beetles to be found on the trunks of the trees during the season of ovipositing. It has even been suggested that children might collect the beetles from the flowers of Golden-rod, to which they seem very partial, and they are also to be found on Sunflowers, probably because the colors are protective. It seems to me that this would be less satisfactory than collecting directly from the bark of the trees they infest.

The beetles are very active, and when alarmed or pursued they will run surprisingly fast or will take to flight. It is generally stated in writings that the beetles are to be looked for in early September, but they should be watched for sooner, as many of them emerge in the latter part of August. Without having noticed or looked for them earlier, I found the beetles ovipositing on August 23d, this season. The eggs are quite large, much larger than might generally be imagined, of a dull white color, oblong and soft, and are to be found just under the edges of the roughest bark, or more particularly in places where the bark has been broken and where small limbs have been cut or broken off. Around the openings of their own burrows are also favorite places of the beetles in disposing eggs.

It will thus be seen that in applying any form of wash to the trees to prevent egg-laying it is extremely important to apply it thoroughly and thickly to all the rougher parts, from well up among the branches to very close to the ground. In this latitude it would appear that the wash should be applied as early as from the 20th to 25th of August. We have known the plan of cutting down badly infested trees to be practiced, trusting to suckers to come up and replace them, but when this is done the diseased wood should be burned before midsummer to prevent the escape of the pests within it.

Of course, it will be difficult to keep the pests in check in districts where Locusts abound everywhere unless radical measures are adopted, but where the trees can be easily numbered, as in most New England and northern towns, they could with a little care be kept comparatively free from injuries. It is particularly important to save and protect the trees when young, for the ravages of the borers then sooner cause their death or so weaken the stems that they break in high winds.

A Blackberry-root borer has appeared in the Arboretum in large numbers this season, causing much injury to the various species of this section of the genus *Rubus*. While it may have been abundant other years it has remained unnoticed, and the

death of the canes has been invariably attributed to winter-killing. An examination of the stumps of the dead canes cut off at the ground, this spring, shows a burrow and pupa in almost every one, the empty pupa-case sticking out of holes in the sides of the canes at an inch or two above the ground. The insects from these pupae are little day-flying moths, known as *Aegeria rubi*. Both at rest and when flying they have a startling resemblance to our common wasp or "yellow jacket," for which they might very easily be mistaken by the casual observer. The moths were found in considerable numbers on August 23d, some of them just emerged, and appearing more abundantly several days later, and when the Blackberry-bushes were vigorously shaken on a warm afternoon many would arise and flutter around. The eggs are deposited soon after this, near the root of the cane; on hatching the young borers work downward, burrowing in the crown or upper portions of the larger roots; they remain dormant all winter, renewing their activity in spring, and finally boring up the canes a little way or merely to the surface of the crown of the root in preparation for emergence late in August. The full-grown larva is about an inch long, of a light yellowish color, with a brownish head. This insect has been called a Raspberry-root borer, but in the Arboretum I have so far only noticed it as infesting roots of Blackberry, although Raspberry-plants are only a few feet distant. There appears to be no remedy for this pest but digging up and destroying the old roots and replacing them with clean young stock. If the old roots are taken up in the spring or autumn and burned, the whole brood of borers will be destroyed, and new invasions will necessarily have to come from other plantations or wild plants. Those who have been troubled with their Blackberry-canecaners not bursting into vigorous growth in the spring would do well to examine the crowns of the roots for borers before jumping to the conclusion that the variety of Blackberry was lacking in hardiness to withstand the cold of winter.

The Rock-garden at Kew.

ONE of the most interesting and popular of the attractions at Kew is the rockery or rock-garden, a portion of which is shown in the illustration on the next page. It was constructed ten years ago on one of the lawns adjoining the hardy herbaceous plant department, near one of the principal entrances to the gardens. The manner of its construction will be gathered from the following extract from the *Kew Report* for 1882: "As the surface of the site chosen was perfectly flat, it was necessary, in order to get any variation of level, without moving large quantities of soil, that the main path through the rock-garden should be sunk. This path was first laid out in a winding course, so as to bring in as natural features the picturesque trees with which the ground was studded. The general idea which was finally worked upon was that of the rocky course of a stream, such as may be met with in some of the side valleys of the Pyrenees. Such streams dry up after winter, and are bounded by rock-piled banks, amid the crevices of which a copious summer vegetation springs up. Above the rocks an evergreen shrubbery growth descends wherever the soil is of sufficient depth. The path, eight feet wide and 514 feet long at the bottom of the rock-garden, represents the dry bed of such a stream. On either side fragments of rock are piled up in a manner as little artificial as was possible to a height of about five feet. Above this the view is limited by shrubberies of Box, Rhododendron, etc., rising to a varying height."

The natural soil of the site chosen was a perfectly pure sand. As much good soil as possible was therefore thrown in behind the rock-bank. As the stones were arranged good soil was worked in beneath and between them. For parts of the banks with a northern exposure tree-stumps were employed. The use of these has been a good deal criticised, but it is not wholly out of keeping with the general idea, and, as a matter of fact, they prove admirably suited to the growth of the larger and stronger growing species.

The principle of a rock-garden is to imitate the conditions of growth of deep-rooted plants. Almost all sub-

Fig. 71.—The Rock-garden at Kew—See page 406.

alpiners are of this character; the distance to which their roots extend makes them to a great extent independent of extremes of temperature and also of drought. They are all, however, intolerant of standing moisture, and flourish best on sloping broken ground from which water readily flows off and does not rest near the collar of the plant and its dormant winter buds.

The variety of conditions afforded by a garden of this character are necessary for the proper accommodation of a large collection of alpine and sub-alpine plants gathered from all parts of the world. The main difficulty is that of atmospheric conditions, which in a flat, low place like Kew are not always favorable to the growth of alpiners. Notwithstanding this, it is surprising how happy many truly alpine plants are in this garden, from the blue Poppy of the Himalayas (*Meconopsis*) and the imperial Primrose of the mountains of Java, to the Pyrenean *Ramondia* and the Pinks and *Campanulas* from the Swiss Alps. Planted in bays left here and there at the foot of the stones are such moisture-loving plants as *Trilliums*, *Arums*, *Hellebores*, and various kinds of bulbous plants, the shade-loving things, such as *Meconopsis Wallichii*, *Ranunculus Lyallii*, *Myosotidium nobile*, *Primulas*, *Ramondia* and many Ferns occupying those parts which are protected from the sun's rays by tall *Hollies*, *Pines*, *Limes*, etc. A bog formed of peat, into which water trickles constantly from a jutting rock above, is devoted to a collection of bog-plants, and in another part an imitation old wall is clothed with *Cacti* and other suitable plants. At the foot of this wall is a peat bed in which hardy *Orchids*, *Equisetums*, etc., find congenial conditions.

Surmounting the bank of stones and in front of the belt of shrubs are such stately plants as *Liliums*, *Cistuses*, *Rheums*, *Arundos*, *Single Roses*, etc., and on the higher mounds, mixed with the bushes of *Box* and small *Deodars*, such striking early summer-flowering plants as *Foxgloves*, *Delphiniums* and big *Poppies* are used with good effect.

Entering at the south end behind some magnificent *Hollies*, one winds along first through Ferns, then into the sunshine, where the sun-loving plants are, the picture ever-changing, yet never flagging in interest until the end is reached. Of course, such a garden is only possible where careful cultivation and constant attention are available. The strong-growing plants must be kept within bounds, and the needs of the small and delicate properly supplied. Without these a rock-garden would soon become a hopeless tangle of weedy plants, but with them it may be made what it is at Kew, one of the most interesting and delightful of the many departments of horticulture.

London.

Cultural Department.

Summer Greenhouse Climbers.

ONE of the best climbers with ornamental foliage is *Abutilon vexillarium igneum*. It is an excellent plant for rafters, as the branches have a drooping habit, and for the same reason it is admirable in hanging baskets. The leaves are small, compared with those of other members of the genus, but beautifully blotched with light and dark green and pale yellow. The red and yellow flowers, produced in autumn and winter, are also beautiful. It thrives well in a mixture of peat, loam and sand, and should never be subjected to a temperature lower than forty-five degrees.

The *Allamandas* are admirable summer-flowering plants. *A. cathartica* is the earliest to bloom, and its comparatively small bell-shaped flowers, of clear yellow color, are produced in profusion. The larger flowers of *A. Hendersonii* are rich golden yellow, and those of *A. Schottii*, perhaps the best of all, bright yellow. These plants require ample room, and are most suitable for covering walls and rafters in lofty houses, though they are sometimes grown in pots and trained to trellises with good effect. They like a moderately rich loamy soil, and in the growing season require plenty of water, with less moisture in winter.

Bougainvillea glabra is a desirable climber, extremely showy, and not exacting in its requirements. On the roof

of a large house, and not trained too rigidly, it grows freely, and flowers profusely during the summer months. The whitish flowers, however, are insignificant, but the large rose-colored bracts which accompany each small cluster make a charming contrast with the bright green foliage. It should be planted in a rich loamy border, with rest in winter. The temperature may then fall to forty-five degrees, and the plant should be pruned moderately before the growth commences in spring.

Cissus discolor is a fine old plant for pot-culture if the stems are trained to a trellis, though it loses none of its attractiveness on pillars, rafters or walls. It is grown for its richly colored leaves, which are of cordate-lanceolate shape, green of various shades, beautifully mottled with crimson and silvery white on the upper surface, and reddish purple underneath. It requires a stove temperature.

Clerodendron Balfourii is another remarkably handsome stove trellis-plant, blooming profusely in early summer. The dark green leaves are opposite and ovate, and the flowers, produced in large panicles, have a conspicuous, inflated, pure white calyx and brilliant crimson corolla. The young growth should be thoroughly ripened after the flowering period by the free admission of air and light; a maximum temperature of fifty degrees will suffice in winter, when water should be given in only sufficient quantity to preserve the wood from shriveling. Prune in the spring, removing all decayed wood and cutting the previous year's shoots back to two or three joints. The weaker ones require to be most severely dealt with.

Dioscorea illustrata is a plant of the same type of beauty as the well-known *Cissus discolor*. The cordate leaves are very large, measuring ten inches in length by six in width, of rich deep green color, with parallel veins and a large central blotch of silver-white on the upper side, the lower one being bright purple. The stems die down annually, and the tuberous roots should be stored in a dry cool place, secure from frost, until the following spring, when they may be potted and placed in stove-heat. *D. illustrata* grows rapidly in rich sandy loam, and has a splendid effect when trained to pillars or columns.

Lapageria rosea is one of the best plants for a cool house—that is, one which is kept as cool as possible by shading and airing in summer, and warm enough in winter to exclude frost. Its ovate-lanceolate leaves are dark green and glossy, and the large waxy flowers deep crimson, with a profusion of small white spots on the interior. Portable specimens may be produced by cultivation in pots, but the plant is more thrifty when grown in a specially prepared border and trained to the roof of the house. The drainage should be perfect and the soil rich and porous. Good fibrous peat and well-decomposed cow-manure, both in pieces not smaller than a good-sized hand, with a liberal admixture of lumpy charcoal and sandstone, form a first-rate compost, which should be firmly pressed about the roots. The young shoots which start from the soil are by far the best, but they have a deadly enemy in snails. The ravages of these pests may be prevented, however, by placing a large rough band of cotton-wool around the base of each shoot, renewing it when it becomes saturated with moisture. *Lapagerias* dislike strong sunshine, and they should therefore be shaded at all seasons during bright weather. *L. rosea alba* is a white-flowered variety fully equal to the species in merit, and the two plants make a pleasing combination when grown together.

Plumbago Capensis is very effective on walls, and is a mass of bloom all summer. The flowers are of a charming pale blue shade, produced in large, dense, terminal clusters. The plant should be pruned pretty closely after the flowering period, and kept dry at the roots in winter. It succeeds well in a cool temperature, but abundant light and sunshine are essential to the best development of flowers, and a rich sandy loam is all the roots demand in the way of soil. *P. Capensis* may also be used to ornament low outdoor walls in summer. The plants for this purpose should be grown in pots, plunged in the soil at the base of the walls to be covered, and wintered in a cool greenhouse or a light airy cellar.

Rhodochiton volubile is exceedingly graceful in habit. It is admirable for rafters, to which the main stems should be trained, allowing the shorter branches to hang downward. These branches are clothed with pale green, cordate leaves, from the axils of which proceed the flowers, borne on long, slender pedicels. The plant is in bloom at all times, and the flowers have a prominent bell-shaped calyx of rosy color, and a dark purple, tubular corolla. The temperature of the house in which it is grown should never be allowed to fall below forty-five degrees, and it should be planted in a mixture of rich loam and leaf-mould, in equal parts, adding sufficient

sand to keep the mass porous. Great care should be exercised in watering, as the plant invariably "goes off" if the soil becomes sour to the smallest extent through excessive moisture, though it may be speedily replaced, as seedlings grow rapidly, and the seeds are freely matured.

Solanum jasminoides is another good cool-house plant. It is a free grower, and makes a singularly elegant covering for columns or rafters. The flowers, borne in large pendent clusters, are bluish white, often pure white, with a showy bunch of yellow stamens in the centre of each. The plant will make satisfactory progress in any ordinary potting soil, but preference should be given to that of a loamy character.

Stephanotis floribunda is an old and deservedly popular occupant of our stoves. The large oval leaves are opposite, leathery in texture, and of deep green color. The tubular flowers, with spreading five-lobed limb, borne profusely in large axillary clusters, are pure white, of waxy substance, and deliciously fragrant. It is an admirable plant for any purpose in which a climbing plant may be utilized, and grows well in any compost, the chief constituent of which is rich loam. When grown in pots—for which purpose it has no rival in beauty—it should be rested in winter and pruned sparingly, removing, however, all superfluous material. After repotting in spring, the old stems and branches should be carefully trained to a trellis, allowing the young shoots, when they appear, to twine around strings attached to the roof of the house. It flowers more freely where this system is followed, and the new branches can be taken down and attached to the trellis, just before the flowers expand, without serious trouble.

Stigmaphyllon ciliatum, the Golden Vine, a somewhat uncommon but very attractive plant, requires an intermediate temperature. It soon covers a large area, its cordate, ciliate, pale green leaves forming a close mass. The large *Oncidium*-like flowers are of deep golden-yellow color, and freely produced in clusters of fair size. It thrives vigorously in a mixture of loam, peat, leaf-mold and sand.

Tacsonia Van Volxemii is a magnificent plant, with flowers resembling in shape those of the Passion Flower, to which, indeed, it is closely related. They are from four to five inches in diameter, and deep rich crimson. The plant should be trained in the same manner as *Rhodochiton volubile*, and thrives satisfactorily under the same conditions, adding peat to the compost.

Cambridge, Mass.

M. Barker.

Roses.

AT this season there is but little to be done among outdoor Roses, except to give the usual attention to cultivation and watering, the latter being of no value unless done thoroughly, while the cultivation is especially necessary during dry weather. As the nights become cooler the Teas will produce better flowers, but it should always be remembered that outdoor flowers, as well as those grown under glass, will be much improved by being cut early in the morning and immediately placed in water. This method improves both the size and color of the flowers, besides making them more durable.

Hybrids for early forcing will now be ripening their growth, and will naturally need less water in order to hurry this process, for it will be remembered that the earliest crops require much more time for their development than those that more nearly approach the natural flowering season.

The most serious pest the Rose-grower of the present day has to contend with appears to be the nematodes, or eel-worms, to which frequent reference has been made during the past year in GARDEN AND FOREST and other horticultural journals. Unfortunately, no specific has thus far been discovered for this pest, the various so-called remedies having all failed under the careful tests of specialists. The most reasonable suggestion that has been offered for their destruction is that of baking or cooking the soil before placing it in the Rose-beds; but this is an operation of considerable magnitude even in a small establishment, and where Roses are largely grown it becomes a very formidable undertaking. It has been suggested that a portable oven of large size and heated by means of steam-pipes would solve the difficulty; but the expense of such an arrangement would work against it in many establishments, especially in those in which the present heating apparatus is not suitable for such purpose.

Lime in various forms has been given thorough tests in several places during the past season and apparently has no effect whatever on the eel-worms, and tobacco extract (which has also been recommended) has not proved any more effectual.

The beautiful Tea-rose *Cornelie Koch* is more rarely seen since the advent of the *Bride*, which is a much freer bloomer.

During hot weather the *Bride* is of little value, however, and then *Cornelie Koch* proves quite useful. In the winter *Cornelie Koch*, though producing large and fine flowers, is not to be compared with the *Bride*.

At least one of the new American pedigree Roses has attracted some attention from cut-flower growers, for I recently saw a bench one hundred feet long filled with *Golden Gate*. The grower seemed well pleased with it, and claimed it to be of about the quality of *Safrano*. The flowers of *Golden Gate* are not very large, but are pretty in the bud, and the plant is generally well spoken of as an outdoor bedder.

Another new Rose of much promise, though not of American origin, is *Empress Augusta Victoria*, a hybrid Tea that was slightly tested last winter, and will have more extended trial during the coming season. In color, this rose is white, and the flowers are shaped somewhat like those of the *Bride*, the petals having good substance, and in addition to this the blooms are delightfully fragrant. The growth of this variety seems strong and the foliage is of good texture, while much is claimed for its free blooming.

It seems unfortunate that so promising a variety as *Waban* once appeared to be should have proved so unsatisfactory as it has done. It is possible that all the fault did not lie with the variety, as it is more than probable that over-propagation so enervated the stock as to injure what might otherwise have been a useful variety.

Holmesburg, Pa.

W. H. Taplin.

Iris Lorteti.

THIS most beautiful Iris, belonging to the *Oncocyclus* section, was discovered some years ago between Meis and Hounin, in South Lebanon, by Dr. Lortet, the accomplished naturalist of Lyons. It was described by Barbey, *Herborisations au Levant*, p. 178, 1882, who there gives a large colored figure of it. Thanks to the unwearied zeal of Mr. Max Leichtlin, a considerable stock of roots has recently been imported from Palestine.

The *Oncocyclus* group of Irises is best known through *Iris Susiana*, which has been in cultivation in western Europe for more than two hundred years, and is still more widely grown than any other member of the group. *I. Susiana* has its home in western Persia, and stretching away toward the Caucasus lives the next best-known, *I. Iberica*. This part of the world may, indeed, be regarded as the centre of the group, and as we pass westward along the southern regions of Asia Minor we find several forms, more or less closely allied to *I. Susiana*, all of them beautiful. Near Mardin grows the lovely *I. Gatesi*, not far off the striking *I. Heylandiana*, more to the west, in Cilicia, the handsome *I. Saari*, and in Palestine is found an Iris which, sent to me from the neighborhood of Nazareth, I exhibited at the Royal Horticultural Society some two or three years ago under the provisional name of *I. Saari*, var. *Nazarena*.

Iris Lorteti, in general features, comes very close to *I. Saari*, and especially, perhaps, to *I. Nazarena*, but its wonderful coloring puts it by itself as, perhaps, the most beautiful Iris in the world. In the specimens gathered by Lortet, the outer segments are described and figured as showing a very pale blue ground covered with crimson spots, which, scattered sparsely over the marginal parts of the fall, are concentrated into a dark crimson patch or "signal" in the centre beneath the end of the style; the inner segments, or standards, are similarly described as being of a delicate pale rose. In a plant flowered this summer by me, the falls showed a creamy yellow ground marked with crimson spots, concentrated at the centre into a dark crimson signal, while the standards were nearly pure white, marked with very thin violet veins hardly visible at a distance.

I learn that the plants imported by Mr. Max Leichtlin show considerable variation in color; apparently, however, the "note" of the plant is a peculiarly charming combination of crimson spots, and blue or violet veins, on a white or creamy yellow ground.

The flower figured by Barbey is as large as that of an ordinary, or rather smaller *I. Susiana*. It is perhaps hardly necessary to add that the flower has the characteristic features of its allies; an oval fall convex from side to side as well as reflexed vertically, bearing a loose beard of scattered hairs, an orbicular, erect standard, and a nearly horizontal style lying close on the claw of the fall, and bearing conspicuous semi-circular crests.

Barbey describes the leaves as being very narrow, though his figure somewhat contradicts this, and in the plants grown by me the leaves are very distinctly broader and more ample than in *I. Susiana*; indeed, it appears to me to promise a larger foliage than is possessed by any other *Oncocyclus* Iris.

As regards cultivation, I have come to the conclusion that all these Palestine *Oncocyclus* Irises should be treated in this country by the "taking up" method—at least, until they have become acclimatized, if ever they do. But one or two points appear to be essential for success by this method. In the first place, they should be planted quite late—say in October, or even in November, according to climate; this prevents their making any growth of leaves before winter comes on. In the second place, they must be protected during winter and early spring, so that the young shoots receive no injury from frost. As soon as the foliage, after flowering, begins to lie down, they should be taken up, well ripened in a sunny greenhouse, and kept absolutely dry until it is time to plant them again. The object of this treatment is to secure their not making any very active growth until fairly warm weather sets in, so that when they are hardest at work they may be comforted by genial sunshine, and not buffeted by autumn rains and winter frost as they are when they are left in the ground or planted in early autumn.—M. Foster, in the *Gardeners' Chronicle*.

[The natural conditions of climate in large portions of California are such as are required for the successful growth of this beautiful section of Irises which grow under similar conditions to the *Calochorti* and *Brodiaëas*. The *Oncocyclus* Irises would be a gain to the already rich flora of California, and, incidentally, would probably prove profitable plants for export.—Ed.]

Onions at the North Carolina Experiment Station.

IN our Onion tests this year all the varieties grown made a fair crop from the seed, and some varieties, including all the Italian sorts, made a big crop, when the character of the land, a hard-baking red clay, never before cultivated in vegetables, is taken into consideration. In every instance those that were transplanted young made the larger onions. This was true not only of the Italians, but of the Wethersfield Red and Southport Globe, which last, while not growing to an enormous size, made a crop of beautiful onions, and promises, on better soil, to be a fine variety for this climate. All the varieties grown will be exhibited at our state fair, in Raleigh, in October, for the purpose of demonstrating the varieties that can be grown from seeds. We were also pleased with the white Potato Onion. This, of course, must always be grown from sets, as, like the brown Potato Onion, it makes no seed. Our sets were planted in February. They will do better set out here in October or November. This white Potato Onion ought to be a profitable crop for our southern market growers, because of its earliness, and it promises to be a better keeper than the old variety.

On suitable soils I cannot see why the cultivation of the Italian and Spanish Onions, from fall-sown seeds transplanted in February, should not be profitable in the south. Some object to the labor of transplanting, but it is no more irksome than pulling out sets. A shallow furrow is made, the plants are laid along two and a half to three inches apart, with tops all leaning one way, and a little soil drawn over them and pressed tightly with the foot. The thing to avoid is getting them too deep in the ground. This way of planting is more rapid and easy than setting them with a dibble, and they can be put in at a more uniform depth. We propose to plant another crop this fall to show the difference between fall and spring sowing; but there is no doubt that good crops can be grown here by simply sowing the seed in February.

The Mammoth White Pompeii and White Garganus made the largest onions. Queen was earlier and of good size. Barletta matured at about the same season, and the transplanted Barlettas were as large, or larger, than the Queen. I see little difference between Barletta and Marzajola. White and Pink Bermuda made fine crops, particularly the transplanted ones. Giant Rocca is superb and very uniform in size. White Portugal made a fair crop. Wethersfield Large Red was not extra large, but uniform and solid. Southport White Globe is handsome and uniform in size, and, though not so much improved by transplanting as the Italian sorts, is well worth growing in this way. As already remarked, I regard it as very promising for cultivation here, though not so early as some other varieties. The season was later, and the constant deluge of rain kept all varieties growing later than usual, but all ripened well.

Raleigh, N. C.

W. F. Massey.

Torenia Fournieri is so generally classed as a tender annual that it may be well to note that it is apparently incorrectly rated as such. An abundant crop of plants now in my garden

is the produce of self-sown seeds from last year's plants, which indicates that they are properly hardy annuals. The seeds have evidently strong vitality, as they lay dormant in the wet border during the winter and spring, only germinating in July, or, at least, no plants were noticed before that time, and if any appeared they were raked out in loosening the soil.

This is one of the most beautiful and useful of the small annuals, and is too seldom cultivated; at least, it is unfamiliar to others than those accustomed to greenhouse flowers. While it is useful in the greenhouse it is attractive in the borders, and, probably, would long since have been more generally grown out-of-doors if it were understood how easily it is managed. Probably, also, the lack of a common name has militated against it, a taking, easily remembered name seeming to be a necessity if a garden-flower is to be popular, a point well understood by the astute florist. A case in point was recently told me by a seedsman. He one year catalogued a rather novel *Ipomœa* with picture and description, but it met with no notice and practically no sale. The next year it was catalogued as a Morning Glory with the same picture and description, and the sale of several thousand packets resulted. If we are sometimes disposed to criticize the catalogue makers for their plant names, it may be well to remember that this is not an unmixed evil, as gardens are thereby enriched with plants which, offered only under a scientific name, would attract no notice or sale. Good plants in gardens, though wrongly named, are yet distinct gains.

Tom Thumb Dahlias.—Under this name last year an English florist offered a strain of plants originated with Mr. T. W. Girdlestone, a well-known English amateur. These were offered here this season by Messrs. Peter Henderson & Co. The half-dozen plants in my garden prove to be interesting, though taller than expected, being from eighteen to twenty-four inches high. This, however, is not a disadvantage, as, were the plants more dwarf, the flowers would inevitably be spattered with earth by every rain. The flowers are single and of the usual form and brilliant colors of the taller singles. Growing with these are seedling plants of a French strain which are practically of the same type, equally dwarf, showing that the strain is well fixed.

At present the two lots of plants prove that seedling single Dahlias will progress as fast and come into flower as quickly as rooted cuttings or tubers. Of course, Dahlias are late summer and fall flowers, never doing well until the cool nights come, so that if one has facilities for starting seedlings, say, in April, there does not seem any advantage in planting tubers unless some special color is desired. The flower-stems of the dwarf Dahlias are short, making it necessary to mutilate the plants somewhat in securing flowers with sufficient effective foliage. For a low border they are useful at this season either alone or in front of the taller-growing kinds, as they have abundant foliage and are covered with the most effective and brilliant flowers, in grace perfect foils to the somewhat lumpy but favorite doubles.

Correspondence.

Some New California Plants.

To the Editor of GARDEN AND FOREST:

Sir,—This has been a peculiar season in California, but all bulbous plants have prospered beyond expectation. I have some new native plants of this class which may be worth noting.

Calochortus nudus is a rare form with a small lilac blossom much like that of *C. lilacinus*. It is found in damp meadows in high altitudes, but with me it thrives in a sandy loam. *C. Plummeræ* is a new *Calochortus* of the Mariposa section, and of striking beauty. The large shapely cups grew about two and a half inches across, yellow at the centre and a rich shade of purple without, while the entire inner portion is lined with long fine hairs colored like the petals. It comes from the dry table-lands of southern California. Another distinct Mariposa Tulip is *C. macrocarpus*, from the Sage-brush deserts of north-eastern California, the other extreme of the state. In beauty of coloring it rivals all others of its class, being a pale violet. The flower is large, the petals not very full, and the habit poor, as the leaves dry up before the bloom appears, and the stalk is stubby and very stiff. I find one trouble in growing these desert forms of *Calochortus*, and that is a fungus which attacks them when in full leaf and destroys every vestige above ground, and sometimes even descending to the bulb. This fungus comes from their native home and is little inclined to injure other species of *Calochortus*.

Perhaps the most beautiful *Calochortus* of the Mariposa section I have had this year is one allied to *C. venustus oculatus*. In years past I had noticed in some spots remarkably large, finely formed blossoms highly colored and marked differently from the type, but I had attributed this distinction to the sticky clay soil where they were always found. A bed planted with these in the same soil as others continues to show the same attractive characters, and marks it as the choice form among Butterfly Tulips. In this variety the blossom is very large, the outline of the petals full, so that they overlap. The lobe of the petal is creamy, with a band of maroon instead of the maroon eye, and a yellow rim, while the centre shows bright red shadings. The plant is remarkable for its capacity for propagation, as each stalk has from two to four large offsets which become small blooming bulbs the second year. A few bulbs of this would in a few years form a large mass. In a wild state it grows in a sticky wet clay, but it has done as well in the clay loam so well suited to the other varieties of *C. venustus*.

One of the prettiest of the new varieties I have tried has flowers of a shell-pink tint, and between *C. pulchellus* and *C. albus* in form, although when the flower is fully open it shows the stamens and pistil. It is an exquisitely delicate thing, and it thrives well in sandy soil. *C. amœnus* is its name.

Those who admire *Brodiaea laxa* will be interested in *B. peduncularis*, an allied species with the same general habit, pure white flowers, and pedicels elongated, so that an umbel is frequently a foot across. It loves a rich soil and abundant moisture. I found it growing luxuriantly in the gravel in flowing streams and in peat-swamps. As it remains dormant until late, it might do well for spring-planting in the east. *Brodiaea*s, generally, while they will grow in any soil, even the thinnest and poorest, love a rich alluvial soil, and grow luxuriantly in such situations. Wild-blooming bulbs in a single year of cultivation will increase from two to five times in size, blooming proportionally strong. They need good drainage and sunshine, and a shallow soil five or six inches deep is better than a deep soil.

A recent note in GARDEN AND FOREST on *Heuchera sanguinea* reminds me to say that the most admired plant in my yard is an immense one of *H. micrantha*. It is in a shaded spot in clay loam, and a solid mass a yard across. The leaves are always beautiful, but in fall they take on very rich coloring. The separate blossoms are inconspicuous, but make a filmy mass most attractive and useful for bouquets. Indeed, I find great pleasure with most of the *Saxifragæ*s, and there are few of the family that do not merit a place in the wild garden. In California, outside of the coast, it is hard to keep annuals moist enough to thrive during our hot summers, and comparatively few of the host seen in the eastern gardens find a place with us. But from those things which love heat we can obtain a world of satisfaction—*Verbenas* luxuriate, *Cannas* grow like weeds, and all of the composites are in their element.

Ukiah, Cal.

Carl Purdy.

Spiræa Aruncus.

To the Editor of GARDEN AND FOREST:

Sir,—This herbaceous *Spiræa* is a tall rank grower and perfectly hardy everywhere. Its creamy white flowers are very small, but they are crowded in such long, many-branched pyramidal panicles that when in bloom this plant compares favorably with the choicest of the florist's perennials. In south-western Missouri, on the southern slope of the Ozark Mountain, it covers the deep and narrow gulches, or gorges, so prevalent here, and seems to prefer a situation of this kind; for while a few specimens are found on gently sloping hills I have never yet seen one growing on level lands. However, when transplanted to the garden or perennial border, they thrive very well, especially if given partial shade. They are admirable in bouquets, where they serve as a foil to large showy flowers, which never appear so well as when combined with soft feathery flowers that suit their outlines and soften their overbrilliant colors.

Several times they have been enthusiastically praised by visitors born and bred in this part of the country who yet did not recognize them in their new surroundings. One lady made a special trip to ask the name of the feathery plant I used in bouquets, utterly ignorant of the fact that she had passed several score of the plants by the road-side as she came to town. It is not unusual for the country people here to be indifferent to the beauty of their native flowers, but their failure to recognize them when growing with cultivated ones

shows only too plainly how much the popular taste needs to be cultivated.

Recent Publications.

Trees of the Northern United States. By Austin C. Apgar. American Book Company, New York.

Perhaps one-half of our adult male population would be able to distinguish an Oak from a Maple; but those who can tell the difference between a Sugar Maple and a Norway Maple, or between a Spruce and a Fir, not to speak of their ability to identify the different species of Spruces or Firs, constitute a small fraction even of our intelligent people. This would be surprising if their knowledge of other objects which they cannot help seeing and hearing every day was more exact—if the more common birds could be recognized by their notes, or if a "bug" or a "worm" were not about the most definite and specific names they would be able to apply to any individual of the teeming millions of insect-life about them. No doubt, the prevalent system of education is responsible to a certain extent for this general lack of the observing habit—a habit which is an original part of the mental equipment of every child; and if school-training has in any way helped to suppress this inquisitive tendency, those educators are engaged in a worthy work who are trying to introduce into schools a kind of study which goes directly to natural objects rather than to books which treat of these objects. This little volume is an attempt to direct both teachers and pupils in the study of the trees, both wild and cultivated, which are found east of the Rocky Mountains and north of the southern boundary of Virginia and Missouri, and it embraces so large a proportion of the trees which grow south of that line that it will be found a good text-book for the schools of the southern states.

The aim of the book is primarily to promote the study of natural science in the natural way; and trees are selected as its special subject, because they are always and everywhere present, and have a certain interest for everybody. In the ordinary text-books of descriptive botany the parts primarily examined are the flowers and their organs, but as these are generally fugacious, inconspicuous and often inaccessible, in this book the attention is directed to the parts which can be found throughout the greater part of the year, and the parts, really, which every one must become acquainted with who learns even to recognize the different trees. The leaves particularly, the wood, the bark, and, to some extent, the fruit are the characters chiefly noted. There is an artificial key which is very ingenious and which will help the beginner in his identifications; there is a glossary of such descriptive words as are needed, and brief descriptions of the species in their botanical order, with good outline figures of the leaves of every one. In a condensed manual of this sort no two persons would include exactly the same material. We should have preferred, for example, to see more than one species of Tamarisk named, and we feel that the foreign Lindens have not been fairly treated. But the book has been prepared with care and sound judgment, and is plainly written out of the personal observation of the author.

Its prime merit, however, is not in the information it gives about trees, but in the skillful way in which it directs the inquirer to study the trees themselves. The chapter on leaves is truly said to "be devoted mainly to the words needed for leaf-description," and the aim throughout is to teach the learner "to employ his own senses in the investigation of natural objects, and to use his own powers of language in their description." So far as any one does this he is working in the line of genuine scientific research. We cannot all become accomplished scientists in any line, but it is possible for every one to become interested in and acquainted with the trees of his neighborhood, and Professor Apgar's book is the best help available to any young person who wishes to begin this useful and fascinating study.

Notes.

The vintage will be smaller in California this year than it has been for five years past.

Among Palms in commerce *Areca lutescens* seems the most popular in this country, and sells the most readily.

Mr. C. D. Ball, well known as a grower of Palms, in reply to the question whether he had experienced of late much trouble on account of the failure of Palm-seed to germinate, answered in a late number of *The American Florist* that he had. The demand for Palm-seed is so great that it is not easy for

collectors to meet it, and consequently old seed is often worked in with the new.

The famous Black Hamburg Vine at Speddoch carries more than 500 clusters of grapes this year, and some of the larger ones will weigh four or five pounds. Last year more than a thousand pounds of fruit were cut from this vine, and the crop this year will reach at least 1,200 pounds. The girth of the vine, which was originally a cutting from the Hampton Court Vine and set in the early part of the century, is now two feet and four inches.

It is stated in *Meehans' Monthly* that if Kieffer Pears are gathered a little before they are mature and then ripened slowly in a room that is cool and not too dry they will rank as table fruit of the first quality. No doubt, rapid ripening impairs the flavor of some pears, but persons who are familiar with the Kieffer as it is found in the market, will find it hard to believe that any skill can transform it into a dessert pear of unexcelled quality. Its value for canning is generally acknowledged.

Just now the Spice-bush is very attractive, as its bright red fruit shows through the rich green foliage. Indeed, it is beautiful the whole season through. It is among the very earliest of native shrubs to bloom; its leaves are of a fresh color, and free from diseases or insect attacks, and its fruit gives it a new value in autumn. An occasional cutting back will overcome its tendency toward a habit too open, but on the borders of woods or shrubberies it needs no attention, and is always satisfactory.

In the early part of this century extravagant expectations were raised over the possible advantages of soil analysis, and when these high hopes were found delusive a prejudice was excited against all such analysis, which is not yet outgrown. It is pleasant, therefore, to note that some scientists remember that the study of soils may have a practical bearing on agriculture, and Professor E. W. Hilgard's report on the Relations of Soil to Climate, lately published by the Department of Agriculture, will be welcomed as a timely contribution to the subject.

The last bulletin of the New York Experiment Station repeats that there is no question as to the efficacy of the Bordeaux mixture as a preventive of the leaf-blight which has been so destructive to Strawberries in many parts of the country this year. The young plants should be sprayed the first year as soon as they become established, and the mixture should be applied four times during the first season, and at least twice before fruiting the second season. The mixture is now prepared with only half the strength originally used, the formula being two pounds of lime and three pounds of copper sulphate with twenty-two gallons of water.

Urceocharis Clibrani is the name given by Dr. Masters to a hybrid between *Urceolina pendula* and *Eucharis grandiflora*, and originated by Messrs. Clibran, of Oldfield Nurseries, Altrincham, England. Judging from a figure in the *Gardeners' Chronicle* the flowers are curiously intermediate in form between the two parents, and they are very beautiful and interesting. The flowers are borne on ascending stalks as in *Eucharis*, not pendulous as in *Urceolina*. They are pure white, borne in umbels, each one two and a half inches long with a slender tube expanding into a cup-shaped limb. The new hybrid promises to be of great decorative value.

A Belgian horticultural journal, regretting the fact that almost the only creepers used for the ornamentation of houses in Belgium are the Grape-vine, the Ivy and the Honeysuckle, recommends four others as especially desirable. These are the Silk-vine (*Periploca Græca*) of southern Europe and the Orient, a twining shrub of the order Asclepiadæ; the Chinese *Calystegia pubescens*, which belongs to the Convolvulacæ, and is called Bearbind in England, and two of our familiar American creepers, the Dutchman's Pipe (*Aristolochia Siphon*) and the pretty Groundnut (*Apios tuberosa*), which we seldom cultivate, but constantly see growing wild along our woodland fences, with its purplish clusters of vanilla-scented flowers, doubly welcome as they appear late in the summer.

Not many weeks ago the bridge joining Castle Island to the mainland of Marine Park at City Point, in Boston, was completed, and the island was thrown open as a public pleasure-ground. It is twenty-one acres in extent, and, says the *Boston Herald*, on the first Sunday after it was opened it was invaded by many thousands of visitors, who filled it full in every nook and corner. Nothing has as yet been done to give it a park-like aspect, except to burn off its great crops of weeds, leaving the ground for the moment black and bare.

Plans for its adornment are not yet complete, but a drive-way will be carried from the bridge along the shore to a "concourse," which will be built out into the water; a shelter will be built on the point now occupied by the hospital; other desirable buildings will be constructed, and trees in due number will be planted.

According to the *San Francisco Chronicle*, a gourd from Japan is proving valuable for all purposes where a sponge is used. This *Luffa* grows on vines twenty or thirty feet long, and while young it is edible, and when cut up in slices like Okra it is highly prized as a flavoring constituent in soups. When fully grown the interior of the gourd becomes a fibrous spongy mass, and this is separated from the shell and outer flesh by boiling in water to which a large quantity of soda or soap has been added. After being thus treated the resultant fibre is dried, and then takes on a sponge-like appearance. It has been tested in the bath, in the household and in the stable. The hottest water does not injure it. It is very flexible and soft, and it is durable as well. The correspondent who has been making the tests is very enthusiastic over the results, and believes a beginning has been made in what will become a very important industry.

The last number of the *Gardeners' Magazine* contains illustrations of two of the hybrid Sweet-briers which have been obtained by Lord Penzance, one of them, Lucy Bartram, showing finely shaped flowers of an intense crimson, and the other, Alice Bridgworth, being a pleasing shade of rose, while the base of the finely shaped petals is white. The Eglantine has been used both as the seed parent and the pollen parent. When hybrid perpetual Roses are fertilized by the Sweet-brier, the leaves of the resulting hybrid do not have the fragrance of the pollen parent, but in many of the reverse crosses the delicious fragrance of the foliage is retained. Most of the crosses have single flowers, although some of them have two rows of petals. In some cases they have proved perpetual bloomers, and give a fine show of flowers in autumn. Lord Penzance is experimenting with hybrids containing Tea blood, and making crosses of many other kinds, and the results obtained will be looked for with interest by all who love the queen of flowers.

Nicotine, the alkaloid which gives its special qualities to the Tobacco-plant, says Monsieur Jules Rochard, of the French Academy of Medicine, writing recently in the *Revue des Deux Mondes*, was discovered by Poseelt and Remann, and first isolated by Vauquelin in the year 1809. "It is an oleaginous liquid, colorless and transparent, which grows dark and thick when exposed to the air. Its sharp, acrid odor is like that of tobacco; it is burning to the taste, and its vapor is so irritating that breathing is a painful act in a room where even one drop of it has fallen. . . . The different kinds of Tobacco contain it in varying quantities. The black, oily tobacco of the Antilles contains much more of it than the light-colored fragrant tobacco of Levantine countries. Its quantity increases with the development of the plant, and varies according to the tissues of its leaves, thin-leaved plants containing it in smaller amounts than thick-leaved ones. The fermenting process through which tobacco is passed volatilizes the nicotine in part, and thus there is less nicotine in tobacco when it is ready for consumption than there was in the dried but unprepared leaves."

The beautiful model of a typical French farm, which attracted great attention at the Paris Exhibition of 1889, will probably be surpassed next year at Chicago by a "model Washington farm in miniature," which Mr. William L. La Follette, Superintendent of the Agricultural Department in the exhibition of the state of Washington, intends to have prepared. This little reproduction will include "farm-houses, barns, fences and fields of growing grain. There will be fields of summer fallow with tiny gang-plows in the furrows, and threshers, binders and all other farm-machinery will be shown in miniature just as they appear while in use in the far west." Mr. La Follette also proposes to erect a "a large cold-storage safe with glass sides and neatly arranged shelving," in which all the fresh fruits of Washington will be displayed during their seasons. "The collectors in the state will keep a constant supply going to Chicago by fast express. First the safe will be filled with luscious strawberries, and from that on during the succeeding seasons as the fruits ripen the cold-storage display will include all varieties ripening from May 1st to October 30th. This manner of exhibiting fruits," we are told, "will excel anything that can be procured in the way of preserved specimens, although the Commission will have an ample display of all kinds of fruits preserved by the most approved methods."

Taste Indoors and Out.

NOT long ago, in an editorial with the above title, we called attention to the fact that, while the taste of cultivated Americans could be trusted in matters of dress and household adornment, their sense of proportion and appropriateness was not equally developed when it came to the arrangement of their grounds. It was also said that since American men are usually too much occupied to give attention to the planning and planting of their places, it might be well for women to give some serious study to landscape-gardening as an art, so that the surroundings of their houses would be ordered with a taste as sure as that exercised in the selection of a carpet or the hanging of a drapery.

We have received several letters complaining of the rather ungallant statement that hitherto women had not shown themselves great in creating broad landscape-effects, and in a letter from one of our alert correspondents, published two or three weeks ago, we were requested to lay down the fundamental principles of landscape-art, so that studious women might master them thoroughly and avoid in the future such errors as had been complained of. Now, it is impossible to give adequate instruction in landscape-art in "six easy lessons," or to lay down any code of rules which can be adapted to all places and circumstances. Diagrams and planting-plans are useful to illustrate the appropriate or improper treatment of particular places, but they are worse than valueless if they are used like ready-made garments to suit all places which may have any similar features. There are no cast-iron regulations about locating a house or its approaches, or securing the proper proportion and arrangement of grass and shrubs and trees which are to surround it. Perhaps the mistakes which result in spottiness or the grouping together of incongruities do not arise so much from following a bad plan as they do from the fact that the work is done without any plan whatever. The fundamental advice, therefore, to beginners should always

be to have a well-defined plan and then to take no step which is not a clearly justified effort to carry out this design. If it be objected that this counsel is too elementary and obvious to be needed, we reply that so far as our observation goes it is only in rare and exceptional instances that anything like a well-considered plan for the arrangement of private grounds, whether great or small, is studied out and adhered to. Of course, such study should begin with the location and character of the house itself, for no harmonious picture can be developed unless the house and its surroundings are thought out together as a consistent whole. But this having been neglected, the desire for decorating the house surroundings usually manifests itself in the search for beautiful trees, shrubs and flowers. Very plainly it is beginning at the wrong end, and yet it is the almost universal practice to collect a mass of such material as nurserymen's catalogues praise most highly and then wander about the grounds in search of enough open space to hold it all. A composition made in this hurried and haphazard way will hardly have unity, and it will not be likely to satisfy a cultivated taste. When a planter, however, has in mind a clear and vivid picture of the scene he wishes to create, the work of construction is simplified, and his effort to set forth this ideal in lines of living verdure will be a source of constant delight.

But this simple advice to make a plan does not meet the request to furnish a system of rules for guiding the novice in its construction and for directing him how to avoid errors and make the most of his opportunities. This is true. But one who makes an honest effort to work out a design, for all of whose details an intelligent reason can be given,—which shall make a consistent picture, and yet provide adequately for all the comforts and conveniences of a household in the way of buildings, walks, walls and other constructions,—has taken the surest way to acquire a realizing sense of the genuine difficulties of the task before him. Such a one will learn at the outset, even before the questions are settled which decide the essential outlines and framework of the scheme, that there are adjustments and adaptations which baffle his skill. The longer he studies the diagrams of his grounds the more the difficulties will multiply and the more ready he will be to ask specific questions and look for help on definite points. At this stage of progress general directions will not satisfy. The learner does not care to be told that his work should be characterized by breadth or simplicity or restraint. This will not instruct him how he can best keep a proposed lawn-space unbroken and yet make room for a necessary road, or how to provide the best foreground for a superb distant prospect. Suggestive hints can be given about certain kinds of work that will be useful on every place, as, for example, the method of masking house-foundations and connecting the walls with the turf; a few general principles can be stated which should guide in the laying down of roads and paths and matters of that sort, but, after all, each place is a new creation, and must be developed on a motive of its own if it is to have any individual value.

No doubt, the puzzled planner, if he is intelligent and earnest, will soon find himself longing for the counsel of some landscape-gardener of taste and experience, and he will be in a mood to appreciate and follow instructions. This statement is not made for the discouragement of any who have received with attention our original suggestion to give some study to landscape-art. This is the only proper frame of mind for a learner in any art. There will be abundant room for individual suggestion even after expert advice is accepted, and the only way to have an intelligent appreciation of the value of such advice is to give personal study to the problems to be met in any instance. In an early number of this journal (vol. i., p. 3) Mr. Olmsted gave a plan for a small homestead which no one can read without instruction. The specific counsel there laid down may not be available in every given instance, but in a graphic way the treatment of the place calls attention to the class of problems which must be faced whenever a design of any

original value is undertaken, and shows the thorough way in which these problems are solved by an artist with conscience and skill. Since then we have published much to illustrate what we consider good practice and bad in the planning and planting of grounds, and we have added much detailed instruction as to the specific character of various trees, shrubs and vines—that is, the material with which an ideal picture is to be realized in actual scenery. We can think of no better way to help on the novice than by continuing to furnish examples and instruction of the same sort, although well aware that published directions alone will never make an artist. They will realize a worthy purpose, however, if they encourage any one to study these questions for himself, and especially to study nature, where he will be sure to find, if he has a reverent spirit, perfect models and true inspiration.

Promising Grasses.

AT the meeting of the Society for the Promotion of Agricultural Science, held last month in Rochester, Dr. W. J. Beal read a paper entitled "Some Selections of Grasses promising for Field and Lawn." The paper was in the main an instructive record of some experiments made at the Michigan Agricultural College, and our readers will, no doubt, appreciate the practical value of the abstract which follows:

Some seedlings of a glaucous variety of *Elymus Virginicus* were reported to have come very true to the parent plants. When grown for three years beside some of the common or type specimens, they were not only all glaucous, but were more vigorous, averaging one foot higher. This grass is probably not very valuable for fodder, but the point here illustrated is a broad hint to all who are interested in pastures and meadows to be on the alert in selecting forms, varieties or races of grasses which exhibit some merits over others of the same species.

For fifteen years or more Dr. Beal has been raising a selected variety of *Festuca elatior*. The seed came from Kew, England, and seems to be the true variety *arundinacea* of this species. When compared with the type usually grown in this country, the roots are longer and stouter, the culms taller and larger, the leaves much longer, broader, thicker, the panicle more erect and flowering a little later. Plants were exhibited.

Four or five years ago, after careful search, three types of *Poa pratensis* were selected, a very small one with narrow leaves, one of medium size, and a large tall one with very broad leaves. These seedlings come very true to the parents. The smallest one seems best for lawn, the largest for meadows and pastures. A plant of the largest was on exhibition and was three feet and a half high where it had been grown in a crowded condition on stiff clay land.

A better grass to grow in the shade of trees, especially on thin soil for a lawn, is a great desideratum. At the Agricultural College, Michigan, has been such a lawn for twenty-five years or more, seeded with a variety of grasses, among which are several varieties of Sheep's Fescue, probably from Europe. Three years ago Dr. Beal selected pieces of sods from what seemed to be three different plants, all the best for lawn. These have since been grown more extensively. In the original lawn there was much variation and the Fescues were considerably scattered. In such places few of them stuck up in bunches, so disagreeable in a lawn, but most of them had slowly spread till one plant had not infrequently covered a space two feet or more in diameter. A sample of the turf was shown, a foot square, where it had formed a fine light green turf, in a shade so dense and on land so thin and cold that June Grass could scarcely grow at all. The sample was not a dense mat of leaves, such as is seen on good soil in the open sun of a well-tended lawn, but was very satisfactory.

For twelve years or more Bermuda Grass has been spreading more or less in a lawn on sandy land of the Michigan Agricultural College. June Grass, some White Clover and Couch Grass have usually been the mainstays when the weather was favorable, but ten days or two weeks of dry, hot weather have turned the green to brown and yellow. Patches of Crab Grass, Pigeon Grass (*Setaria*) and numerous other dry-weather weeds rendered the surface very unsightly. In several places the Bermuda Grass has spread on the lawn. In spring, and always when the weather is moist and warm enough, June Grass keeps green and makes a fine lawn, the

Bermuda Grass lying low and making little display. On the arrival of a drought, June Grass retires and Bermuda Grass thrives, thus covering the soil throughout the growing season. So far on the college lawn Dr. Beal is much pleased with this experiment of mixing June Grass and Bermuda, but it may not work equally well in some other portions of the northern states.

Indian Ridge—An Experiment.

ONE of the public-spirited men of my acquaintance has been carrying on an experiment in tree-planting and farming on an unpromising lot of about a hundred acres, lying about equidistant from two Massachusetts villages, with the idea that if these towns ever become crowded and flourishing manufacturing centres this estate may some day prove valuable as a country park for both places.

I have found it interesting to observe this place in its various stages during the half-dozen years that it has been under cultivation, and some account of its gradual restoration from barrenness to productiveness may prove of interest also to all those who take an interest in reclaiming waste land.

When the purchaser, whom I will call Mr. X., took up this land it had been well-nigh shorn of its timber. There were some small woods of Birch and Maple, some scattered Junipers, a few good Pine and Oak trees, and a belt of small saplings growing along and in a stretch of low swampy ground that was set down on the old town-maps as Sweet River. Nothing that looked like a stream could, however, be discovered there, its only suggestion was that the water-holes among the peat-bog were a trifle deeper in some places than others.

The first step in the restoration of these waste lands was to provide a protection for these woods from fire, always a menace to outlying timber-land, so in order to form a barrier against the devouring element as well as to drain the marsh it seemed desirable to recover the lost river. An intelligent Irishman was accordingly instructed to re-establish the course of the former stream by trenching, directions being given him to avoid straight lines and to connect the deepest water-holes with something like natural curves.

For two or three summers the ditcher worked away, leaving, at the conclusion of his labor, a winding stream varying from eight to fourteen feet in width, with a dry walk constructed from the peat dug in this manner and thrown on brush, along one edge of it, backed by woods, and on the farther bank a picturesque mass of natural shrubbery full of wild beauty and fragrance. Other trenches connected with this stream rendered the meadow lands available, so that the one job established a good defense from fire, supplied a valuable mass of peat for use upon the high dry uplands, and gave good fields for raising grain or grass, by lowering the general level of the water. This was effected by a system of water-gates permitting the variation of its level at will.

Through the woodlands, for still further protection, the leaves were raked away and trenches cut to help in fighting the flames by isolation, if by chance some of the trees should catch from guns, burning brush on adjoining land, or from the sparks of a locomotive. These precautions are still taken continuously to protect the property from its most dangerous enemy. The next step was to establish nurseries for trees, and to plant them everywhere in great numbers. Mr. X. made the mistake of beginning his plantations with one-year seedlings, which perished in great numbers, but experience taught him that trees somewhat older were of a more satisfactory size to endure drought and the dislodging frosts of a New England climate.

This tract is one of very varied surface, consisting of valley, bog and upland; gravel hills, sand hills, clay hills are all to be found upon it, and in the centre rises an eminence some 125 feet above the sea-level, which commands from its summit a widely extended and beautiful inland view over the neighboring villages as far as the distant hills of Milton.

There is a curious interval in one part of the place, which has been known for the better part of a century as the dry dock, from its resemblance in shape to one of these constructions, the walls being represented by two steep moraines, or, to speak more precisely, kames, evidently the deposit of some break in an ancient glacier. The crest of these Indian ridges, or horsebacks, as they are popularly called, is only wide enough for a foot-path, and they are from two to three hundred feet in length. Their steep slopes are covered with self-sown Junipers. These singular formations are of much geological interest, and as such a double moraine is unknown in this section of the country, this rare phenomenon cannot fail to attract the attention of every scientific observer.

Great Hill is approached from various directions, and its owner has constructed numerous curving roads, one of which leads to its summit, and is planted as an avenue with groups of young trees, and winds among the existing ravines in a way to make use of them effectively. When the present proprietor purchased the property, it was not esteemed valuable, as all the good timber had been cut, and the mossy, arid surface promised nutriment neither for trees nor crops. Mr. X. did not undertake the experiment of reclaiming it for profit, but as an entertainment for himself, as a means of giving employment to people in whom he was interested, and to show what could be done by intelligent management of even so worn-out a region as this. His ultimate aim is to produce a pleasure-ground that may be of public worth in the future, and the whole venture is so public-spirited and so valuable as an object-lesson that it fills the observer with interest.

The gradual transformation from desolation to fertility in this once abandoned spot is a proof that with zeal and energy no part of Massachusetts need go to waste, if people are willing to work intelligently and faithfully for the restoration of its soil. Here, where once all was barrenness, are to be seen fertile fields, reclaimed bogs, neat, well-ordered vegetable-gardens, groups of flourishing young trees, and nurseries wherein others stand ready for transplantation. Where the ground is hilly the moisture runs off, the trees grow slowly, parched by the drying winds and lack of sustenance; but on the level spaces they flourish bravely, and the soil from the bogs helps to feed their roots. In the kindly shelter of light-existing woods the more delicate trees are growing up, their nurses being thinned out as they increase in size. Beeches and Ginkgos, English Walnuts and Paulownia Imperialis flourish under the protection of White Birches, Sweet Gum and Hemlocks, shaded by the kindly Cedars; and an experiment is being made with the Oregon Maple and Acer Colchicum rubrum, which are always planted on the north side of an evergreen.

Pines have been extensively planted all over the place. White, Pitch, Norway, Scotch and Austrian Pines flourish well. European Birches and Sugar Maples are springing up everywhere, alternating with feathery groups of English Larches. Shrubberies also have been set out, where a goodly quantity of beautiful varieties, such as Thunberg's Spiræa and Berberry, Golden Elders and Spiræas, Deutzias, Purple Hazels, Rosa rugosa and Rosa multiflora are mingled with Cornels and Viburnums and many other shrubs. Space, too, is found for the rarer varieties of trees—Golden Elms and Beeches, Cut-leaved Maples, variegated Elms, Golden Hop Hornbeams, Purple Maples in variety, Purple and variegated Beeches, Chinese Cypress, English Alder, Sycamores, Lindens, and numerous others.

The native Junipers are very handsome, and show their usual variety—some dark and blue, feathered like a Cypress, others yellow-green, and more like a Cedar in foliage. Where the swamp was once inaccessible, judicious filling has given access to a pond which is not yet completed, but will add to the beauty of the place, with its irregular outline and overhanging Willows and Maples. The walks about Great Hill are full of variety, whether you climb over the moraines or stroll on the shady hill-sides or mount by the easily winding drive to the very summit to enjoy the view. A visit to the sheep-folds, where the brown-nosed woolly throng come running to be fed, and try to climb the little trees to browse upon such leaves as are just out of their eager reach, is full of amusement. A flock of sheep is always picturesque and entertaining, with its surprised rushes hither and thither, its gentle undulations of closely packed forms, its funny cries of wonder or fright, the merry trotting of the little hoofs, the shy, mistrustful little faces that watch your every motion so carefully. These little beasts are very carefully protected with high fences finished with barbed and netted wire, and with locked gates to shield them from dogs, and they are closely guarded in their passage from run to run, while their folds are strong and dog-proof.

To accommodate the foreman and workmen on this place, which Mr. X. does not himself occupy, he has constructed an immense barn, which, situated at one end of the moraines, has convenient entrances for vehicles on three stories. On one side of this barn two stories serve for a dwelling in continental fashion, and the other affords accommodation for horses, the basement being devoted to sheep and cows. By means of a good system of ventilation, and a series of doors between the house and stable part of this construction, the dwelling is kept free from odors, and is as convenient and comfortable as any farm-house need be, with the added advantage in winter of having everything under one roof, and

entirely under the eye of the farmer and his men, an important thing in an out-of-the-way locality, where depredations might easily take place without attracting attention.

A visit to this barn shows all sorts of modern conveniences and comforts for cattle. Each sheep is furnished with a little rack of his own for his fodder, which he persists in leaving to try his neighbor's, with sheep-like jealousy, lest another should be better provided than he. The spring lambs bring so high a price, if put early enough upon the market, that it makes their raising profitable, though this flock is not very large, numbering about sixty; moreover they are the most efficient means of transforming wild coarse feed into the best manure.

In the course of his experiment, Mr. X. has discovered that raising timber could never be made profitable on land of this kind, from the fact that the original price paid for seedlings, the expense of taking care of them in their infancy, and the interest on the money, added together, would amount to more than the timber would bring in the twenty or thirty years necessary to render it ready for market.

Having, therefore, provided enough trees to furnish an element of beauty for many years to come (the nurseries being still overstocked, in spite of all his planting), Mr. X. has now turned his attention to raising crops that may be valuable while the trees are growing.

The fields are separated by small belts of timber instead of fences, which gives each stretch of open ground the effect of a lawn skirted with forest. Wherever a fine group of trees was found it has been preserved, with its rocks and underbrush, to form a pleasing natural feature in the scene. Many of these fields have been troublesome to clear, and are still rough, but by the aid of top-dressing and such tilling as is possible they raise good crops of Hungarian Millet, Corn, Rye, Alsike Clover and various Grasses. Many of them, however, have been brought into good condition, and the smooth fine curves of the brown soil lying ready for the seed, or the level sheets of vivid green where the winter grain is springing up, agreeably diversify the rolling surface upon which one looks down from the summit of Great Hill.

The stroll along the recovered river is very beautiful, fragrant in July with wild Swamp Honeysuckle and Clethra, and gay with wood-blossoms at all seasons of the year. Water-lilies and other aquatic plants flourish close to the shady banks just out of reach, and the fairest blossoms blow always on the other shore. Lovely Ferns spring in these solitudes, and the Swamp Rose grows tall and shows its pink blossoms and slender leaves above the surrounding herbage. Here and there a glimpse of sunny meadow meets the eye on the other bank of the stream as you cross its tributaries on primitive bridges, and brush away the tangle of verdure from your path. At your side the Swamp Maples grow tall, and birds sing in their branches. As you walk, there is revealed to you what is seldom seen, the lovely heart of a swamp, with its lush vegetation, its dark, cool recesses, its lonely, shadowy nooks where man rarely penetrates. This river-walk, reclaimed from the peat-bog, is one of the most pleasing of the various attractions of the Farm of Indian Ridge.

I have said enough to show that if a need for a park should ever be felt in its region, we have the beginnings of a delightful one here. With open ground for playstead, and ample room for all sorts of amusements in addition to commanding views, it could be easily made a delight for two contiguous towns, from neither of which it is more than a mile away.

Such enterprises as these are valuable to the observer, and promise well for the future of the country.

Hingham, Mass.

M. C. Robbins.

Edible Fruits in the Pines.

SIX months in the year, at least, an abundance of wild fruit can be found in the Pines, some of which is very good in quality. The wild strawberry has an exquisite flavor, and with cultivation the size of the fruit is increased without loss of the delightful aroma. The best berry is borne by *Fragaria Virginiana*, which we readily recognize by its deeply pitted fruit and narrow neck, and the soft silky appressed hairs on the fruiting stems. Other kinds grow here which it is difficult to identify. I think, however, many have escaped from cultivation and are reverting to the original type. The Shad-berry, or June-berry, ripens before the strawberries are gone; they are sweet and rather pleasant to the taste, although they lack character and sprightliness. We often find the two in company—ripe June-berries hanging over strawberries. Wild Raspberries follow these, but neither the black, the so-called white, nor the red varieties have as fine flavor as those which grow farther north. And yet the cultivated Raspberries of southern New Jersey are specially good.

Early in July our low Blackberries or Dewberries ripen, and some of them cannot be surpassed anywhere. They are large, juicy, sweet and of exquisite flavor. The common high Blackberry is at home here, as it is everywhere. The fruit, which ripens in August and September, is plentiful and of excellent quality. We also have the low Sand Blackberry (*Rubus cuneifolius*). The fruit of this species is in perfection a little earlier than that of the tall Blackberry. The berries are shining black, of good size, and of delicate flavor. This species does not extend very far north. It is found only sparingly in the southern part of New York and Pennsylvania, thence extending in sandy districts mostly along the sea-board to Florida. We find, too, the running Swamp Blackberry. The fruit of this species is small and sour, and by no means tempting to the palate, but the vine is evergreen and very ornamental, especially in autumn and winter, when most of the leaves take on their bronze and scarlet hues; others, however, retaining their shining green color throughout the winter season.

Several kinds of Blueberries and Huckleberries grow in the Pines. The earliest is *Vaccinium vacillans*, which is very plentiful in the dry sandy barrens. It is a foot or two in height, and ripens its fruit early in July. The tall Swamp Blueberry (*V. corymbosum*), with its many varieties, is very abundant in the swamps and damp places. The size and quality of the fruit vary greatly. I have sometimes found the berries as large as good-sized cherries on tall bushes in damp woods. These large berries remind me of a fright I experienced some years ago. A party of us were in the woods in Atlantic County, not far from Egg Harbor River. I had wandered away from the rest to a thicket of the largest huckleberries that I had ever seen, nor have I since seen their equal. They were growing on tall bushes far above my head. I was intent on examining and testing the fruit, bending the bushes down and breaking off the twigs here and there, with which to surprise the rest of the party, when on looking up, not more than a hundred yards distant, I saw distinctly a large black bear standing on his hind feet eating huckleberries like myself. Which was the more astonished or frightened, Bruin or I, it would be hard to tell. At all events, he came to his senses sooner than I did, and dashed off through the thicket, making a crashing noise as he went, leaving me almost paralyzed with fear. This incident, occurring in one of the oldest states of the Union, in the very heart of civilization, gives some idea of the extent of the swamps and woodlands that still remain here.

We have another class of Blueberries which differ somewhat from *Vaccinium*. They belong to the genus *Gaylussacia*, and are distinguished from the other species by having ten seeds which are quite large compared with the numerous tiny ones of *Vaccinium*. One of these, *G. dumosa*, is a half-creeping, dwarfish plant, sending up fruiting stems six to eighteen inches in height. It has racemes of very pretty open bell-shaped white flowers, often tinged with pink. The fruit is shining black, of good size, but flat and insipid. The Dangleberry (*G. frondosa*) is very abundant. The fruit is blue, with a white bloom. It is sweet and is usually found in market mixed with the Swamp Blueberry (*Vaccinium*). The black Blueberry (*G. resinosa*) is also abundant. This is more of a dwarf species than *G. frondosa*, and the fruit is black, without bloom, and has a more delicious flavor than the former. We sometimes find a form of this with handsome white berries, one side with a pink tinge. The Cranberry is found in most of the bogs, and in some places is quite plentiful.

The Chokeberry (*Pyrus arbutifolia*) is everywhere in damp places. The fruit is red, sometimes bluish; it ripens in August, but is not very good. The Beach-plum is also found here. The fruit, though it varies greatly both in size and quality, is better than the Chokeberry. Some of the plums are scarcely worth the gathering, while others are large and luscious, and most tempting to the thirsty passer-by. The bushes never attain the size of even a small tree. The Wild Cherry assumes such fine proportions as to make a handsome ornamental tree, and its fruit, while not to be despised by human mortals, is a constant source of temptation to the birds. I have planted several Cherry-trees and some of White Mulberry for the sole use of my feathered friends.

Wild Grapes are numerous, and the Summer Grape (*Vitis æstivalis*) makes excellent jelly and wine. The Frost Grape (*V. cordifolia*) is quite palatable after frost. The Persimmon forms thickets in many places. The fruit usually ripens after frost, though I have occasionally found trees with fully ripened fruit before frost. When ripe it is orange-yellow, soft and sweet, and relished by many.

Crab-apples of poor quality we find scattered about. If we had nothing better they could be utilized in making jellies and preserves. The Prickly Pear grows in the dry Pines. The

fruit is edible, and will make nice-looking jelly. The barbed prickles with which the plant is armed are annoying to one who gathers the fruit, and I cannot recommend it in the face of so many small fruits which are greatly superior for household purposes. The aromatic Wintergreen is everywhere in the damp Pines, and in the autumn it gives employment to many poor people, especially Italians, who gather the fruit for market.

Vineland, N. J.

Mary Treat.

Native Shrubs of California.—VII.

ONE of the delightful unfading pictures in our memory of eastern woods in their June glory is that of the shrub or small tree known as Flowering Dogwood (*Cornus florida*). A full-grown specimen, with its widespread and stratified branches, each ultimate twig bearing a large white cruciform involucre which commonly passes for a corolla, is an object of striking beauty in the forest-glades where it occurs. *C. florida* was one of the earliest of American shrubs to find a place in the parks and shrubberies of Europe; several varieties, one with red floral bracts, and another with drooping branches, are now generally offered by nurserymen at home and abroad.

We have in California a second species of Flowering Dogwood, *C. Nuttallii*, Audubon (*Birds*, 467). This is superior to the eastern species, at least in point of size and speciousness. Though commonly enough a shrub of fifteen or twenty feet in height, *C. Nuttallii* is sometimes a tree of fifty or sixty feet; its white floral bracts, not rarely two or three inches long, are in sixes, not fours, and the whorl, or "flower," is therefore five or six inches broad, and circular rather than cruciform. The oldest trees do not, to my knowledge, present that stratified arrangement of branches, as I have called it, which marks the eastern species; but at all stages of development its head is more compact and massive; moreover, the flowers are not borne in the same profusion as in the older eastern trees. *C. Nuttallii* is, nevertheless, really one of the beauties of the forest in several sections of California and Oregon. Late in April of the current year, while passing along the elevated mountain-road between Knight's Valley and Lakeport, near the summit of a ridge leading up to Mount St. Helena, on rounding an abrupt bend in the road which brought me at once from the dry southward to the cool moist northward slope, I was brought to a sudden halt, struck with wondering admiration as I saw before me a half-dozen fine young trees of this species in full bloom. And, as if to intensify the happy impression of an old-time woodland scene in New England, I found, as I came near the trees, the ground beneath them half-covered with the ample spotted foliage of one of our western *Erythroniums*, *E. giganteum*, a plant as much larger than the eastern Dogtooth Violet as the western Dogwood is larger than the New England tree, the flower-stalk supporting from three to six pale yellowish or almost white blossoms.

This Dogwood is said to have been formerly indigenous to the San Francisco peninsula. If this is true, no specimens have been allowed to remain, though few of our native shrubs could be more worthy of preservation for ornamental purposes. A group of these planted in our Golden Gate Park, or a single one of them in any private shrubbery, would elicit praise from all admirers of beautiful trees if seen in flower, while even the fruit, a close globose cluster of scarlet berries, coming on late in summer, is singularly attractive.

The brilliancy of Poppies has been appreciated in many parts of the world from immemorial ages; and not until after the discovery of California were any shrubby genera of this family known. *Romneya*, with its fine sea-green foliage and enormous white flowers, is now familiarly known and much admired both at home and abroad. I like quite as well our other shrub Poppy, the *Dendromecon*. This has not yet been added to the list of cultivated shrubs in even our own country, though its merits were recognized in Europe as soon as the first pressed specimens for the herbarium had been seen there. The flowers of this are yellow, and resemble those of the *Eschscholtzia*, but the foliage is entirely different, being narrow and willow-like, and clothing all parts of the bush up to the base of the slender flower-stalks.

One of the prettiest contrasts, in a floral way, which the Coast-range landscapes afford, is seen where, as on Mount Tamalpais, long stretches of bushy slope exhibit a commingling of the intense blue of a small *Ceanothus* and the rich yellow of the *Dendromecon*.

All our native shrubs, in so far as they have been made the subjects of such experiment, respond quickly to the cultivator's efforts, in an increased luxuriance of foliage and greater profusion of bloom, and I am confident that any one who

might succeed in propagating our neat yellow-flowered shrub Poppy, and introducing it at home and abroad, would have done floriculture a great favor. A demand for this, equal to that which has been created for its more pretentious ally, Romneya, would surely follow. The seeds of *Dendromecon*, like those of Romneya, probably require a long time to germinate. From seeds sent to England by David Douglas sixty years ago a few plants were produced, all of which are said to have been killed by the severe winter of 1837-8. I think that no subsequent attempts at cultivating it have been successful there, if, indeed, any have been made. In California I have never been able to record the germination of a single seed, whether sown in garden or greenhouse.

University of California.

Edward L. Greene.

Notes on the Flora of Smythe County, Virginia.—V.

THE aspect of the country north of Marion was strangely different from that of the district on the North Carolina border. Walker Mountain, the first range of hills on the left bank of the Middle Fork of the Holston, a straight, level, almost unbroken mountain-range, is covered with a young forest, which, though hardly as beautiful as the wilder ones across the river, was not, however, lacking in interest. Innumerable little brooks danced and sparkled down through the dells and valleys, each of which had more or less distinct features, and often a flora of its own. This was especially marked in the cryptogamic collection that we made. Sometimes a tiny Moss or Liverwort would grow on the stones of a little water-course, which, even with careful search, could not be found elsewhere. One quite large stream, in spite of its odd name, Hungry's Mother Creek, was a very attractive feature in the landscape, flowing between tall cliffs and broad meadowlands, the cliffs covered with a luxuriant growth of Ferns, and the meadowlands filled with tall Grasses and Sedges and bordered with high tangles of superb Blackberry-vines, the flowers of some of which were remarkable for their strong resemblance to Apple-blossoms. They were very large, with the outer surface of the white petals a bright rosy pink. In one of the meadows we found the tall pale lilac-blue spikes of the Wild Hyacinth, or Eastern Camass (*Camassia Fraseri*), and along the shady hedges the very local *Hydrastis Canadensis*, a plant with a coarse broad leaf and very inconspicuous flowers and fruit, grew with quantities of *Polemonium reptans* for its companion.

On the rather barren mountain beyond we found an interesting form of the Dwarf Thorn (*Crataegus parvifolia*) not more than four feet high, with thick bright green glossy leaves; the rather large white flowers growing in clusters of two and three, and remarkable for the multiplicity of their petals, some of them having as many as fifteen. Higher on the mountain *Crataegus coccinea* grew in great abundance, and with it its so-called variety, *macracantha*, the leaves of which are broader and darker than those of the type, and having apparently a more spreading habit of the branches. *Pinus pungens*, the Tablemountain Pine, covered with its many generations of large cones, was occasionally seen, but the Scrub Pine (*P. inops*) was the common Pine of the range. In the woods *Euphorbia corollata* was just coming into bloom, and *Ligustrina actæifolium*, a coarse umbelliferous plant, grew side by side with some very tall and beautiful Meadow Rue (*Thalictrum purpurascens*).

The golden *Coreopsis senifolia*, var. *stellata*, was seen scattered in small groups, a most effective plant. *Aletris farinosa* was with it, though not in abundance. *Galax aphylla* covered the ground in places, and was always pretty with its light green glossy leaves and slender white spikes. Near the top of the mountain, clumps of *Tephrosia Virginiana*, with yellowish, pink and purple pea-like flowers, were conspicuous. The bare reddish sandstone ledges on the top of the mountain were decorated with innumerable pretty white stars of a Saxifrage and quantities of Ferns and many Grasses. *Hydrangea arborescens* was flowering, its broad white cymes having somewhat the aspect of those of *Viburnum lantanoides*, though the flowers were by no means so handsome nor so large. *Heuchera pubescens* was with the Saxifrage on the rocks, and along the banks of the road which descended into the valleys of the North Fork of the Holston River we passed through great hedges of the pretty pink-belled *Apocynum androsæmifolium*. In the woods three Milkweeds were in bloom—the greenish Poke Milkweed (*Asclepias phytolaccoides*), *A. variegata*, a handsome plant with white flowers, and *A. obtusifolia*, with rather dull purple and greenish flowers. Near the river and in open fields the gorgeous Butterfly-weed (*A. tuberosa*) made brilliant orange spots in the landscape. The shallow borders of the river were filled with the Water Willow (*Dianthera*

Americana), a slender erect plant with long narrow leaves and purple and white spotted flowers. Some very fine specimens of the Ash-leaved Maple, then in fruit, grew along the water's edge, and in the open fields, struggling through the short grass, we found the small *Galium Anglicum*, an introduced and very diminutive species, scarcely more than two inches high.

North of Saltville, in the Holston valley, the two nearest and highest elevations are White Rock and Red Rock, presumably named from the color of the perpendicular cliffs that crown their summits. The excessive heat rendered the ascent of White Top, the loftier of the two peaks, a somewhat formidable undertaking. The road followed a narrow rocky water-course for a mile or two through woods and along open clearings, where thousands of Chinquapin (*Castanea pumila*) made the atmosphere almost stifling with the far from pleasant odor of their flowers. On some of the ledges we found the graceful, drooping flowers of *Dicentra eximia* and very large spreading plants of *Arabis lyrata*.

Most interesting at that altitude and so far inland was a small grove of Holly (*Ilex opaca*). The shrubs were quite high and very handsome. The American Mistletoe (*Phoradendron flavescens*) was noticed on some very tall trees, but was totally inaccessible. When the road grew too narrow for travel we left our wagon and climbed the long steep ascent which wound through ravines and woods till it reached a clearing hidden in a shallow hollow of the great mountain. Two small cabins, surrounded by poorly cultivated Rye and Corn fields and savoring strongly of the moonshiner's retreat, stood under the shadow of a few giant Tulip and Chestnut trees. Other trees still larger lying on the ground told a tale of the grandeur of the past forest, the prostrate trunks surpassing in size any that we had previously seen. From that point our path was a hardly visible trail through underbrush and young woods with interesting and often familiar plants all around us. On damp ground we found the blue-flowered *Phacelia* (*P. bipinnatifida*), a plant having less beauty, however, than the other two species, *P. Purshii* and *P. fimbriata*. One of the commonest of the smaller flowers through the county was *Houstonia purpurea*. Everywhere it bloomed, a delicate pinkish purple, but in the White Rock Woods we found it pure white. *Hydrophyllum macrophyllum* and *H. Canadense* were growing together, and open fields below the cliffs were purple with a *Pentstemon* that we were not able to name with the literature at hand. Our literature failed us, too, with a large, very showy *Rudbeckia* that was beginning to fill the woods with yellow. A few early specimens of the red *Lilium Grayi* were collected, and innumerable buds just ready to open promised a gorgeous sight a few days later. *Clematis Viorna* grew up there taller and with larger flowers than any before seen, its pink-purple bells being much more than an inch long and broad in proportion. The large blue Spiderwort (*Tradescantia Virginica*) was scattered everywhere, and *Vicia Cracca*, a pretty little Leguminous vine, climbed over the taller herbs.

The last part of the climb was up the precipitous cliffs that formed a sheer barrier along the summit of the mountain. The rocks were covered with a white Lichen, the color of which could be seen miles off from the valleys, giving its name to the mountain. From the top the view in all directions was magnificent. Southward we counted eight ranges of tree-covered mountains, White Top and Mount Roger towering above all, while a dim vision of the great masses of Grandfather and the Roan faded into the distant horizon.

The mountain sloped gradually into the valley beyond, and the whole summit was a flower-show of the most brilliant description. Without leaving the highest point of the rock we could see many acres of Flame-colored Azaleas (*Rhododendron calendulaceum*) in full bloom. They were not more than three to five feet in height, but were unsurpassed in color. Every shade and gradation of yellow, orange, scarlet and crimson were represented in all their infinite variety. *Amianthium muscætoxicum*, a tall, slender liliaceous plant, with spikes of white flowers, grew among the Azaleas. It was interesting to find many of the earlier-blossoming plants still flowering at that altitude. A few *Kalmias* were still seen; *Pyrus nigra* was abundant, and so was the tiny flowered *Ilex monticola*, as well as a low form of *Andromeda ligustrina*, that was covered with small white bells.

The long valleys around Saltville were more remarkable for their large stock-farms and cultivated fields than for botanical purposes, so on our return from White Rock we did not linger, but retraced our steps across the Walker Mountain to the Marion valley. Our time there was limited, and we were obliged to return east without seeing the wealth of summer and autumn vegetation, the coming glory of which was

already prophesied along every road-side and in every field.

The mountains of the south-western portion of Virginia, as well as those farther south and west, are yearly becoming more accessible to travelers, and their great charm and beauty are sure, before long, to make the tide of spring and summer travel turn in their direction. Away from the railroads, accommodations are scarce and usually of the most primitive description, but beauty of scenery, superb views and the intense quiet of the great forests make up to a degree for the lack of luxury.

The mountaineers were invariably civil and hospitable, and readily shared their simple fare with us. Even the suspicious moonshiner would travel out of his way to show us a short cut. Great was the interest shown in our strange employment, and speculations were rife as to our reasons for wishing to carry away the useless weeds which grew in such profusion along the slopes of every hill.

New York.

Anna Murray Vail.

January, produced vigorous plants, which began to flower in 1886, and have flowered profusely ever since. The flowers are large and dark-colored, but not larger, or of a deeper shade, than those of many cultivated Peach-trees. The fruit is free-stoned, rather thick-skinned, with white juicy flesh; it has a fair flavor and good size, as is shown in the illustration on this page from a drawing made in the Arboretum by Mr. Faxon. The fruit, however, is not remarkable in quality, although rather better than the average, nor is it remarkable in size, and the only peculiarity of this variety which deserves attention is its great vigor and hardiness. The flower-buds of the Peach-tree are often killed in this latitude; and in eastern New England the peach-crop is very uncertain, the trees rarely producing more than one crop of fruit in four or five years. But up to the present time the flower-buds of this Chinese variety have

Fig. 72.—A Chinese Peach.

New or Little-known Plants.

A Chinese Peach.

IN the autumn of 1879 Dr. Bretschneider, the distinguished botanist and Chinese scholar, and at that time an attaché of the Russian Legation at Peking, sent to the Arnold Arboretum the seeds of a number of trees and shrubs gathered on the mountains near the Chinese capital. Among them was a package of peach-stones labeled "Cultivated Peach, growing wild." These seeds, planted in the following

never been known to suffer, and year after year the branches are covered with flowers and abundant crops of fruit. Here, then, perhaps, is a variety from which seedlings can be raised which will be as hardy as the parent, and which, by careful selection, will produce in time fruit of first-rate quality, or which can be used by the hybridizer to give vigor and hardiness to a new race of exceptionally hardy Peaches. The quality of the fruit is already good enough to justify the effort to improve it; and the trees in the Arboretum offer to pomologists of cold climates the op-

portunity to extend northward the territory in which the Peach can be successfully and profitably grown.

This Pekin variety is of interest, too, as a probably direct Chinese descendant of the wild Peach, which is now believed to have come originally from northern China, whence it was early transported by the way of India into Persia and other countries of the Orient, and then into Europe and North America.

Dendrobium Phalænopsis.

THE figure on page 440 was prepared from a good variety of this beautiful *Dendrobium*, now in flower at Kew. The plant is one of the large number imported by Messrs. F. Sander & Co. from New Guinea last year, and sold by auction. A full account of this species will be found in volume iv. of GARDEN AND FOREST, page 521, written immediately after the sale of these plants. Since then this Orchid has gone forward in popular favor. It is not only the best of the Australian *Dendrobiums*, but it is one of the very best of the several hundred species known. The only correction I would like to make in the account published last year is in the statement that Reichenbach was responsible for the varietal name, *Schroederianum*. On inquiry I learn from Messrs. J. Veitch & Son, Chelsea, that the plant thus named was imported by them and sold to Baron Schroeder. It was the finest form of *D. Phalænopsis* known prior to the importation of Messrs. Sander & Co., and, no doubt, the name was given when it flowered in the Baron's collection to distinguish it from the plant flowered at Kew and figured in the *Botanical Magazine*, t. 6817, which has shorter pseudo-bulbs and smaller flowers, much paler in color than those of Baron Schroeder's plant. The statement made recently in *Reichenbachia*, that all the plants, including that of Baron Schroeder, were offshoots from the plant flowered at Kew, is therefore incorrect, as, indeed, a comparison of the figure in the *Botanical Magazine* with that of Baron Schroeder's plant, published in *Reichenbachia*, conclusively shows. No doubt, the newly imported plants were designated by the varietal name for trade purposes, but now that so many forms both in regard to size of pseudo-bulb and flower as well as color are known, the name *Schroederianum* may conveniently be dropped.

The plant figured here has pseudo-bulbs a yard high and as thick as a man's thumb. The flowers are three inches across and colored mauve-purple, with a deep maroon-purple labellum. The oldest flowers have been expanded a month, and they are still fresh.

For its cultivation *D. Phalænopsis* requires the hottest and moistest stove, and it grows best when placed in a position close to the roof-glass. Messrs. Sander & Co. recommend for it the treatment of the Pine-stove, or such as suits *Crotons* and *Ixoras*. The Kew plants are grown in baskets, and are planted in peat-fibre and sphagnum. They are liberally watered and syringed overhead when in growth, and are kept moderately dry after the growth is matured. It may be stated in proof of the good nature of this *Dendrobium* under cultivation that the plant sent to Kew by Mr. Forbes ten years ago is still in good health, and has flowered this year.

Water-lilies.

POND-LILIES have always been popular flowers, and their cultivation in natural and artificial basins is by no means new, but their ornamental capabilities have been appreciated for comparatively few years. Though grown for a long time in botanical collections, their decorative value seems to have been first realized by Mr. E. D. Sturtevant, who less than twenty years ago began to impart his enthusiasm for the plant to others and started the movement which has resulted in the present interest in aquatic plants in this country. Many grand varieties were then in existence, but they were not of a char-

acter to appeal to the general garden public, being mainly tender kinds, or supposedly tender, as in the case of *Nelumbium speciosum*, needing special care and facilities possessed by few growers. Of hardy White *Nymphæas*, there was a fair number of varieties, but the discovery of the red sport of *N. odorata* on Cape Cod, and the introduction of a red variety of *N. alba*, from Lake Fayer, in Sweden, after a few years quickened the interest very materially. About the same time Mrs. Mary Treat discovered the half-hardy *N. flava*, which had first been made known by the brush of Audubon. And at last we had a collection of hardy varieties from which, under the quickening hand of the hybridist, there have been produced new varieties of the greatest interest and merit.

Mons. B. Latour Marliac has especially distinguished himself in this line, his *N. chromatella*, introduced in 1887, being, with *N. sulphurea*, introduced about the same time, the first of a series of fine varieties as yet unsurpassed in shades of yellow and pinks. They appear to be mostly hybrids of some form of *N. alba*, and in the case of the yellows, either *N. flava* or *N. Mexicana*. One of the newer ones, *N. helveola*, is a beautiful yellow, while the newest variety, *N. Laydekeri*, is apparently a cross between *N. pygmaea* and *N. Sphærocarpa*, the Swedish Lily, showing the peculiar color at one stage which characterizes the latter variety. The Swedish *Nymphæa* is one of my failures, it declining to move for me, but from information received from correspondents I am inclined to believe that the peculiar changes of coloring of *N. Laydekeri* in the different stages of the flowers is a peculiarity inherited from *N. alba rosea*. The new pink *Nymphæas* have, I think, all been described in GARDEN AND FOREST during the season, and it will suffice to say that there is at present available a whole gamut of tones, from faintest blush to light carmine. But there is evidently a number of important additions to come, if I may judge from the flowers sent me during the season. After a little experience in growing pink *Nymphæas* in different soils and different seasons it has been impressed on me that one can speak of them only as they average, and that caution is required in describing the color of varieties from slight material. From Mr. Sturtevant I have had fine flowers of a new variety, a bold solid flower with broad petals and a very clear, uniform suffusion of pink of a delicate shade. There came from Dr. H. T. Bahnsen a flower of similar character with a tinge of salmon. Both of these are very promising. Monsieur Marliac has two new *Nymphæas* which he claims are hybrids of *N. chromatella* fertilized by *N. rubra* of India. As they are said to be as hardy as *N. chromatella*, with deep carmine flowers of the largest size, they will add a new zest to water-gardens next season. From William Tricker there comes a new hybrid tender *Nymphæa*, evidently *N. dentata*, colored by *N. rubra*, which gives a new night-blooming variety with the bold loose habit of *N. dentata*, of a light rose shade, which should light up well. As a friend says, the possibilities of hybridization among the *Nymphæas* seem infinite, and constant accessions of new and desirable hybrids may be expected to crowd our collections.

Choice Hardy Plants.

FROM early spring until late in the fall, our herbaceous borders are made bright and attractive with some species of the Speedwell family. In the early summer a large number of the European species are in bloom. *Veronica longifolia subsessilis* is beautiful at this time. In my estimation it is the best of all the hardy *Veronicas*, and deserves a prominent place in our borders. This Speedwell was introduced from Japan in 1878; it is quite hardy, easily propagated, and has large, conspicuous racemes of blue flowers. It is scarce, and not often enough seen in collections of hardy plants. It grows from two to four feet high; its serrated leaves are from three to four inches long and a deep dark color. The flowers are of the deepest blue and are produced freely in large dense racemes. The plant has good habit and is easily increased by division of the roots early in the spring or late in the fall. It thrives best in a good, deep, rich soil, and prefers an open situation. This is altogether a good perennial and deserves a place with our choicest hardy plants.

Young plants of *V. longifolia*, raised from seeds sown last spring, are blooming profusely now, and the long racemes of blue flowers are very effective. Although this is the most common species in gardens, it is, nevertheless, a handsome border-plant, and grows and flowers freely in any good soil. Another Speedwell in bloom is *V. Virginica*, the large Virginian Speedwell. In color, its flowers are not as pleasing as those

already described, but it is a bold and stately plant and well deserves a place in our gardens. The plants in bloom here are between four and five feet high, and the lanceolate, serrated leaves are produced in whorls along the stems. The flowers are arranged in long panicles and are of a whitish color. It is a free-growing plant and likes good, rich soil.

Sedum spectabile is grown in the herbaceous border in large clumps two feet across, and the clumps are planted about four yards apart. This method of planting is very effective, and will give a display for five or six weeks. This is one of the best of the tall-growing Sedums we have; it stands drought well, is a good bloomer, quite hardy, and is never much attacked by insects. It throws up erect stems about eighteen inches high which are furnished with broad glaucous leaves. Even before the plant blooms it is conspicuous for its showy glaucous leaves. The large massive heads of small rosy flowers, which are arranged in cymes from five to seven inches across, are very attractive and are noticeable from a distance. The plant will grow and flower in the shade, but for perfection it requires to be planted where it will have the full benefit of the sun. It will grow rapidly if planted in good rich soil, and is easily propagated by division of the crowns in spring. It is a native of Japan. Another good Stonecrop in bloom is *S. Ewersii Turkestanicum*. It belongs to the evergreen class of Stonecrops, and is a neat dwarf plant, somewhat like *S. Sieboldii*, but more compact in habit. It is quite hardy and an excellent rock plant. The long, prostrate stems are covered with smooth glaucous leaves, about an inch across; the lower leaves are elliptic and the upper ones heart-shaped. The flowers are dark red-purple and are produced in terminal corymbs. It is easily increased by division or by sowing seed early in the spring. The species of which this plant is a variety is a native of Siberia. The plants in bloom here were raised two years ago from seed obtained from Mr. Thomson, Ipswich, England.

Plumbago Larpentæ has been in bloom for more than a month, and will keep on producing its violet flowers until frost comes. It was introduced into England from China in 1846, and was grown in greenhouses before it was known to be hardy. When this plant first flowered in England, a year after it was introduced, a small plant with three or four blossoms was shown at a meeting of the Horticultural Society by Lady Larpent's gardener, and was awarded a prize. The judges at once saw the good qualities of this *Plumbago*, and declared that it would become a good bedding plant. Soon after this it was found to be quite hardy, and *P. Larpentæ* was soon generally grown. Plants in our rock-garden have stood for several years, and produce annually an abundance of beautiful flowers. *P. Larpentæ* is dwarf, with prostrate wiry stems about a foot long, covered with leaves about two inches in length. The flowers are produced in trusses at the ends of the slender shoots and are an intense violet color. It does best in a raised position in the

rock-garden, where there is plenty of light and sun. It is easily increased by division, either in spring or fall.

Balamacanda Chinensis, better known in gardens under the generic name *Pardanthus*, is quite hardy and grows into large plants here without any protection. It is a herbaceous plant, growing about three feet high, with root-stock and foliage like an Iris. The flowers are orange-yellow, and mottled above with crimson-purple spots. They are rather fugitive, but, as they are produced abundantly, the plants are at no time without

Fig. 73.—*Dendrobium Phalaenopsis*. Half natural size.—See page 439.

flowers during their blooming season. It thrives best in a rich sandy soil and in a situation where it can get plenty of light. Seeds are produced abundantly, and these germinate quickly after they are sown. On a recent visit to a nursery near by I saw thousands of these plants, raised from seed sown last spring.

In the back row of the herbaceous border, the most showy plant is *Rudbeckia subtomentosa*. Without a doubt, of all the tall-growing *Rudbeckias*, this is the most compact plant

and the best for our borders. It is not too tall. The stout stems, with their ovate-lanceolate leaves, rise to a height of four or five feet and are branched at the top. On these small branches the bright yellow flowers are produced in large numbers. It is found wild in the western states, growing on the prairies and in open moist grounds. It grows best here in deep, stiff soil and away from the shade of trees.

Botanic Garden, Cambridge, Mass.

R. Cameron.

Fall Work.

THE potting of various bulbs for winter and spring flowering should now be attended to. Among these are *Lilium longiflorum* and *L. Harrisii*, the latter being the more easy to force early in the season, though for early forcing medium-sized bulbs are preferable, and Bermuda-grown stock is usually superior to that cultivated in this country. The best soil to use is a light rich loam, with a liberal addition of good manure. The bulbs should be potted quite firmly, and at least one inch below the surface, as the stems will send out roots above the bulbs if they are planted deep enough, and the bulbs should be placed at once in the pots where they are to bloom. After potting it is best to place these Lilies out in a cold frame until they are well rooted. During this period I prefer to cover them with shaded sashes instead of burying the pots in soil or ashes, which tends to weaken the growth.

Tulips, Hyacinths, Narcissi, Freesias and other Dutch bulbs will soon be received. With all these root-action must be secured before the tops are forced into growth, or the flower-spikes will be weak. *Gladiolus Colvillei* should be included in the list of bulbs for winter and spring. Its handsome spikes are a very acceptable addition to the stock of flowers for cutting.

Quite an industry has been established of late years in the growing of seeds and bulbs in California for the eastern market. Among these are *Calla* bulbs of excellent quality, furnished at reasonable prices. Some of these may well be included in the fall bulb order, as the California bulbs seem more floriferous than the home-grown article, possibly because they are more thoroughly matured. A few bulbs of *Amaryllis aurica* will also prove a satisfactory investment. Their bright flowers are a pleasing addition to the conservatory, and no special nursing is required to induce free and vigorous growth.

The removal of tender plants from the flower-beds will soon be necessary, at least in northern latitudes, and cuttings should be secured of *Geraniums*, special varieties of *Verbenas*, *Coleus* and other soft-wooded plants, to make sure of some of them before an unexpected frost arrives. The compost-heap must be prepared before the ground becomes soaked by the fall rains, and it is better to attend to this matter during the summer months, when the soil is in the best condition.

The lifting of *Carnations* and *Chrysanthemums* planted out-doors may be done whenever the weather is favorable, if possible, during dull weather. The plants will then suffer very little, though, like many other simple operations, much depends on the after care. I have seen *Carnations* transplanted when the ground was so dry that it was impossible to lift a ball of earth with them, and yet by careful treatment the plants did well, while others, lifted under the most favorable conditions, failed from lack of thorough watering in and frequent syringing overhead for the first few days. *Bouvardias* should also be lifted soon, and may be either potted or planted on a bench, the latter system usually inducing the strongest growth and greater quantity of flowers.

Holmesburg, Pa.

W. H. Taplin.

Anemone Japonica.—Too much cannot be said in favor of this Japanese *Anemone* for piazza decoration, grown in pots. It is very easy to grow, and can be stored in a cold cellar in winter. To have flowers in August it is necessary to start the plants in a cold frame in March, and to plunge them in the open ground after danger from frost in May. When the plants show their flowering stems in July a little liquid manure will strengthen them.

Phlox Triomphe du Parc de Neuilly is the brightest and best of all the scarlet shades of herbaceous *Phloxes*. For two seasons I have saved seeds and raised about one hundred seedlings from this variety, but not one in any way resembled the parent, although they were very beautiful.

Clematis paniculata will be in magnificent bloom here by the 12th of September, and no doubt it is in full flower already in the latitude of New York. This is one of the best species ever introduced, and seems free from disease. It has, moreover, a very sweet hawthorn fragrance.

Funkia subcordata grandiflora.—This beautiful Day Lily is grand when it succeeds well, as it does with us. Plants in partial shade do better than those in the full sun. It is perfectly hardy, but suffers in sunny places from alternate thawing and freezing in spring. The young leaves are also very liable to injury from late spring frosts. I saw a magnificent clump a few days ago, and I should think it could be very effectively used for massing in public parks. Prior to the blooming season its handsome foliage is very effective.

Wellesley, Mass.

T. D. Hatfield.

Correspondence.

Water-lilies at Yarmouthport.

To the Editor of GARDEN AND FOREST:

Sir,—For many years Water-lilies have been a special feature in the gardens of John Simpkins, Esq., of Yarmouthport, Massachusetts, and representatives from all parts of the world are found here in one or the other of the three spacious tanks. The newer hybrids and varieties are grown and tested as soon as sent out. For one interested in *Nymphæas* no better opportunity for studying them can be found than this collection offers, and no more willing or capable guide than Mr. Brydon, the gardener of the establishment.

Nymphæas may very conveniently be divided into day-bloomers and night-bloomers. Among the tropical and sub-tropical species and varieties (all of which are bulbous-rooted), *N. gigantea*, introduced from Australia as long ago as 1852, is one of the handsomest and best of those which bloom by day. It is comparatively rare, principally on account of the difficulty of keeping it over. It is also very impatient of being disturbed, especially when small, and until well established it is liable to go to rest, forming a poor bulb, or a number of small ones. The flowers are violet-blue, with a deeper border along each petal, sometimes measuring ten inches in diameter, and standing boldly out of the water. The flower is, unfortunately, inodorous. *N. Sturtevanti*, said to be a chance seedling from *N. Devoniensis*, is remarkable for its handsome reddish brown leaves. The flowers resemble those of *N. Devoniensis*, but are more double, the multiplicity of petals giving them an incurved form, and one fully open measured twelve inches in diameter. *N. stellata Zanzibarensis*, introduced as recently as 1880, is a well-known sweet-scented day-bloomer, and produces an abundance of large flowers of the deepest blue. The typical variety is a long time opening its flowers, and opens them later in the day than do its seedlings, many of which are very handsome, and range in color from blue to pink and purple. *Azurea* and *Rosea* are named varieties of this species. *N. Lotus dentata* is a variety with chalk-white flowers of the well-known Egyptian *Lotus*. It is a night-bloomer, and the flowers are star-shaped. *N. Devoniensis*, a garden variety, originated at Chatsworth, England, is one of the brightest and best. Its bright red flowers are produced out-of-doors until very late in the autumn, and with the protection of a greenhouse it will bloom all through the winter.

Of the newer hardy, or nearly hardy, species and varieties, all of which are day-bloomers, Dr. Bahnsen's *Nymphæa Carolinensis* deserves to rank with the best. It is a supposed natural hybrid, with a rhizomatous root like the common *N. odorata*. The flowers often measure seven inches across, of a light pink when they open, and changing to white. *N. alba candidissima* is a splendid variety of the common European *N. alba*. It is sometimes confounded with the American *N. tuberosa*, but is quite distinct in that its flowers are more double, a purer white, and it possesses a running rhizome. Some of the dwarfer kinds are very pretty and interesting, especially in showing the wide range of form in the genus and in giving a certain completeness to a collection. *N. Mexicana* is a dwarf and pretty free-flowering yellow species, and very fragrant. It resembles *N. flava* somewhat, but the flowers are larger and stand more clearly out of the water. Mr. Brydon is of opinion that this species, instead of *N. flava*, is one of the parents of *N. sulphurea* of Marliac. *N. sulphurea* possesses many of the characteristics of *N. Mexicana*, especially in the long petals, the longer rhizome, and the habit of the flowers, which stand clear above the water. *N. pygmæa* is a neat little central Asian species introduced into Europe in 1805. It is white-flowered and very fragrant, and, according to Mr. Sturtevant (*American Florist*, August 18, 1892), is one of the parents of Marliac's *N. Helveola*, and *N. flava* the other. *N. Helveola* resembles *N. Mexicana*, but the flowers are shorter and less double.

Many of Marliac's new varieties have proved equal to his representation. *N. exquisita*, evidently related to *N. odorata*, is

one of the best pink-colored hardy varieties grown. *N. carnea* is a light pink. *N. rosea*, with flowers seven or eight inches across, a lovely shade of pink, has also very handsome foliage. *N. albida* is a splendid white. The flower is better than that of the variety *Candidissima*, but Mr. Brydon says it is not so satisfactory to grow.

A disease which, unfortunately, disfigures the leaves has attacked the *Victoria regia*, and, consequently, it is not so handsome as it once was. Rand's variety is grown, and is distinguished from the type in having a deeper rim to the leaves. The Sacred Bean (*Nelumbium speciosum*) is quite at home in a pool along the edge of a swamp, and, judging from the growth it is making, would soon cover a large territory.

Wellesley, Mass.

T. D. H.

Scab-proof Apples.

To the Editor of GARDEN AND FOREST:

Sir,—The relation of the Apple-scab fungus to the different varieties of Apples is an important one, and is worthy of careful investigation. Dr. Hoskins, in GARDEN AND FOREST for August 3d, p. 370, thinks one of my statements in the issue of June 29th, p. 310, is too emphatic. I said then there are no varieties of market apples in western New York which are not subject to the attacks of the scab fungus. The statement is a strong one, but I intended that it should be. Since Dr. Hoskins has commented upon it I have reconsidered it carefully. I have also visited many orchards in western New York, and a few days since I had the good fortune to be visited by one of the mycologists of the Department of Agriculture. We examined Baldwin trees in a commercial orchard, the Baldwin being, perhaps, as nearly scab-proof as any of our market varieties. The foliage was comparatively small and gray, and stiff from the attacks of the fungus, and many of the fruits themselves were scabby. I am convinced that my former statement is true—that we have no market apples in this region which are not subject to the scab to a detrimental extent. In some years nearly all varieties escape, and some varieties are more free from scab than others; but there are years in which all suffer, although not, perhaps, to an equal extent.

I cannot admit that the liability to attack of scab is an indication of a "constitutional defect" in such variety. I have not yet seen any facts which would lead me to think that the fungus attacks the less vigorous or less hardy varieties, using the term hardy in its ordinary sense in the north, as an ability to withstand untoward circumstances of climate and surroundings. I have not found that there is any decadence in the constitutional vigor of varieties, as a whole, in recent times.

One other important consideration must not be overlooked here, and that is the fact that enemies often progress or develop as rapidly as do the host plants. I imagine that by the time we are able to breed scab-proof varieties—from the present standpoint—our scab-fungus will have developed a capability to attack more uncongenial hosts. This is the common history of injurious insects and fungi; they take on new habits to accommodate themselves to new conditions. It is possible that a good market apple may spring up which is for the time scab-proof; but when we have learned how to produce such kinds with tolerable certainty, the enemy will have grown cunning too, I fear. How many are the Pears which are sent out as blight-proof, and yet in a few years they suffer with the rest. We are in the habit of distrusting the originator who makes this claim if it turns out false in after years, but I am inclined to think that some of these varieties really are measurably blight-proof at first. If the histories of varieties of fruits could be written from the natural-history side, I fancy that many of our notions would be upset.

I would not discourage Dr. Hoskins' efforts toward scab-proof apples, but I am not over-confident of success. For my generation, at least, I must pin my faith to the squirt-gun.

Cornell University.

L. H. Bailey.

The Ten Mile Woods of Hartford.

To the Editor of GARDEN AND FOREST:

Sir,—At the north end of Hartford, within the limits of the city, begins a stretch of woodland interesting alike to the student in natural science and history. The Tunxis, Podunks and Poquanak Indians roamed in these now utterly neglected woods, which reach out toward the ancient town of Windsor. A large variety of native New England trees and shrubs grow here in natural profusion and beauty; wild Grape-vines encircle the trunks of forest-giants, and berries of all kinds make luxuriant growth. Cardinal-flowers are just past their best bloom.

There are Asters of many colors, and the white and blue Gentian and the later fringed Gentian are abundant. Wild Lilies thrive in the rich earth, and our American *Nelumbium* decorates the still waters of the lakelets. In the spring the ground is covered with *Hepatica*, *Trailing Arbutus*, *Trillium*, *Jack-in-the-Pulpit* and *Dog-tooth Violets*. Ferns grow luxuriantly, the common *Bracken* pushing up to a height of six feet. There are, besides the rare and beautiful climbing Fern, various *Polypodiums*, *Osmundas* and *Maiden-hairs*. On the sand-dunes the pink and blue *Lupines* flourish, and the clear and cold trout streams are bordered with Sweet Fern. The stately heron is at home in this tangled wild wood as well as all the song birds of the region.

Old residents remember these woods when they extended nearly a mile farther south than their present limit, and within my recollection they have been encroached upon from all sides by clearings for agricultural purposes and by newly built homes. There is left, notwithstanding the willfully arranged annual spring and fall fires, a large tract of this desirable and valuable forest. The Charter Oak City should acquire and own that portion, now private property and subject to such destructive treatment as the whims and necessity of the present owners may direct. Some months ago, on the recommendation of a number of citizens, the City Council took favorable action in the matter of securing a tract of land near Trinity College for park purposes. At that time the local press urged that large outlying tracts be purchased by the city and connected by improved road-ways, so as to make a continuous drive leading up to the Ten Mile Woods, and Mr. Frederick Law Olmsted clearly stated the desirability and value of such ownership and improvement.

Nothing has been done, however, toward preserving this natural inheritance, which, properly treated, would be not only a beautiful park and woodland, but would have a distinct value for botanical study. In my opinion, too, if this forest were managed on the most approved principles of forestry, its products would make the purchase a profitable investment for the city. To the generous and patriotic tribute to our national defenders in the soldiers' monument, the city should add the purchase of the Ten Mile Woods, as an enduring, living monument to peace and education.

Hartford, Conn.

Wilhelmina Seliger.

Shrubs for a Screen.

To the Editor of GARDEN AND FOREST:

Sir,—The entrance to my place is a bank about seven feet in height above the road, with a very sharp slope toward the entrance-drive and a gradual descent on its other side. It is about one hundred feet in length. I would like to plant it out so as to give as much as possible the effect of retirement and privacy. On the opposite side of the drive is the gate-lodge, low and simple, and the surroundings are of the rather poor Oak-forest, indigenous to the south side of Long Island. The character of the country is such that this entrance should be unobtrusive and not accentuated by masonry.

I should like your advice as to the best shrubs to use in planting. *Rhododendrons* are not suitable, as they only do well here when shielded somewhat from the north winds and the sun, and they also require a location where the moisture does not immediately run off, as would be the case on the bank in question. You will, I think, agree with me that, in such a position as I have indicated, an evergreen character is desirable—or, at any rate, that shrubs should be selected which retain their foliage late in the season. I do not fancy conifers for covering the bank, although a few might be judiciously introduced. It may be added, that the situation is favorable for a carpet of *Periwinkle* where desired.

Oakdale, L. I.

C. B. W.

[It is not easy to give a planting list for a place which one has never seen, but it seems that the desire of our correspondent for unobtrusive plants could not be better obtained than by using largely some of our native deciduous shrubs. *Viburnums* and *Cornels* are good to begin with, and among these we would suggest *Viburnum dentatum* and *V. casinoides* as having the best foliage, while *V. Lentago* could be used where taller growth is wanted. Among the *Cornels* could be used *Cornus sericea* and *C. paniculata*, with *C. stolonifera*, and more especially *C. alba*, to brighten the shrubbery with their stems in winter. Several of the *Barberries* might well be introduced, and an occasional plant or two of *Leatherwood* would help to make the

shrubby interesting by its early flowers in spring. Sumachs make a good covering for banks, but the Staghorn Sumach is of too rank a growth to be planted with the shrubs already mentioned. We have seen excellent effects produced by using together three native species with *R. typhina* for the background, followed by *R. copallina* and *R. glabra*. *R. aromatica* is well suited for planting on banks. It is not easy to get satisfactory shrubs for this region which keep their leaves late in autumn, but the Privets are suitable for such a situation, while the showy-fruited and almost evergreen *Cratægus pyracantha* would probably do well. Too great a variety is not advisable where a quiet unobtrusive effect is desired, but Wild Roses might be introduced among a planting of Cornels, *Viburnums* and the like.

Rosa Wichuriana, which has been frequently mentioned in our columns, would probably prove a good plant for covering the ground instead of the Periwinkle. It might be used alone in covering a bank, or it will grow if planted among tall shrubs, in which case many of the stems will clamber up along the branches. It would very quickly cover a bank in the climate of Long Island and would prove practically evergreen.—Ed.]

The Skimmia.

To the Editor of GARDEN AND FOREST:

Sir,—*The Garden* (London) of August 13th has an illustration of *Skimmia fragrans*, which shows a very attractive plant, but the text does not give all the information concerning it that is desired. I turn to Nicholson, and find under the proper head: "A genus comprising half a dozen species of pretty, hardy evergreen, highly glabrous shrubs, with green branchlets, natives of the Himalayas and Japan. Flowers whitish, clustered; calyx short, four or five lobed; petals four or five, oblong, much longer than the calyx, valvate or loosely imbricated, etc." The fruit of the species *S. Japonica* is described as bright red in March. This account, taken in connection with the article in *The Garden*, indicates an interesting group of which but little is known.

Newport, R. I.

L. D. Davis.

[Trials of the *Skimmias* at the Arnold Arboretum have not proved them satisfactory plants there. Several forms have been tested, but as yet they have shown themselves rather too tender for the climate, in spite of winter protection. If they survive the winter, the blossoms are hurt by spring frosts, and the showy fruit does not follow. We observe that several nurserymen of the southern and middle states advertise these plants, and we should be obliged if any of our readers who have tried them will give the results of their experience.—Ed.]

Nature Study, for the Common Schools. By Wilbur S. Jackman. Henry Holt & Company.

The publication of this book and many others on kindred topics is an evidence that the study of natural science is making steady progress in our public schools and that kindergarten methods are growing in favor among the better class of educators. Professor Jackman, however, has not made a textbook in the ordinary sense of the word; his work gives little or no information on the subjects treated, advances no scientific theories, makes no attempt to deduce scientific laws; but aims simply to show how one teacher awakened a love of nature study in the pupils entrusted to his care by an intelligent use of materials taken almost at random from Nature's own workshop. In fact, the writer seems little troubled by theories of any kind. He has no preconceived ideas as to the proper order of development of the childish faculties, nor does he advocate any formal or logical sequence of studies to which everything must bend; he merely notes the eager curiosity with which the child examines every object in the world about him; that impartial interest which turns with equal zest from the pebble at his feet to the rainbow in the sky, and supplying it with abundant materials for observation, he makes its instinctive delight in the natural world a stepping-stone to the development of the higher faculties.

The introductory chapters treat of the motive for "Nature Study," and the various modes of developing the child's powers of expression, which should always go hand-in-hand with the acquisition of knowledge, but the body of the book consists of a series of graded lessons in botany, zoölogy, physics, chemistry, meteorology, astronomy, geography, geology and mineralogy, the subject-matter of which is adapted as far as possible to the changing seasons of the year. As the school world begins in September, it is the vegetable and animal life of September, the September storms and the September sky which the child is first called upon to notice, and thus he learns to note in turn the peculiar influence of each season upon all the world within his range of observation. These lessons consist chiefly of sets of questions stimulating and suggestive enough to awaken interest even in children of a larger growth, and, in the hands of an enthusiastic teacher, they must make the hours spent in such study one long delight. It is enough to fill one of the older generation with surprise, although not with amusement, as he reflects that, according to modern theories, that part of his knowledge which he can least afford to lose was acquired not while sitting on hard benches in poring over lexicons and text-books, but in the long stolen rambles over the hills, through sunny meadows or by tempting brooks, every hour of which had the exquisite flavor of forbidden fruit, and gained in charm from the thought of the reprimand, and perhaps the punishment, in store when the truant returned to the neglected duties of the school-room. Whether the rambles and the birds-nesting, the expeditions in search of fruit or nuts will not lose something of their charm now that they are incorporated into the school curriculum, is a question we leave to philosophers, but to the layman there can be no doubt that a scheme of instruction which recognizes and provides for the development of all the faculties must in time produce a race of men and women more fully equipped for the struggle of life, in which, according to Darwin, the race is always to the swift and the battle to the strong, than the time-honored system of our forefathers, which regarded the alphabet as the key to all knowledge worthy of the name.

For the method of study set forth in this volume we have only praise, but it may be questioned whether the motive to which Mr. Jackman seems to appeal in his effort to awaken a love of nature is the highest that can be offered. It seems like putting a premium upon one kind of selfishness to say that the individual's own life is the centre of all his interest in the world, and that how to prolong it should be the ultimate aim of his study. This is only partly true. The instinct of self-preservation is so strong that every individual early learns to adapt himself to his own environment, while the special knowledge which has enabled man to control and direct the forces of nature, and so enlarge the sphere of human activity, has been gained by scientists who, through their long years of toil, thought their own lives of little value in comparison with the service they could render to their fellow-men. In the study of science, as in all else, he who would seek to save his own life must lose the higher joy, and a knowledge of Nature's laws gained solely for this purpose will prove rather a snare to its possessor, revealing, as it will, the thousand roads that lead to the shadow from which he is trying to escape.

Most of those who study science in our public schools are doomed to lives of monotonous toil, beginning often before the years of childhood are past. In these lives of toil self-interest must be the prevailing motive. The knowledge the pupils can gain in school must necessarily be limited, and can go but a little way toward softening their hard conditions. The true teacher, then, during the years in which the child is under his care will strive to implant that impersonal love of nature which lifts its possessor for the time above all sordid and material interests, and gives him that refreshment of the spirit which comes only when thought of self has been laid aside.

Notes.

We have observed several *Kolreuteria* trees near this city which appear to be suffering from some blight. In one or two cases nearly all the leaves have fallen to the ground.

The *Southern Lumberman* takes a strong stand in favor of the Paddock Bill for the establishment, protection and administration of public forest-reservations. It also states that the suggestion in this paper of establishing a forest-reserve in the southern Alleghanies is warmly seconded by the timbermen of the south-eastern states.

A writer in the *Pomona Progress*, basing his estimates on the profits of his own Prune-orchard and the figures given him by four of the most careful growers in Pomona Valley, California, makes the rosy statement that ten acres planted with French Prunes will, within ten years, yield an easy annual net income of \$5,000. The outlay for such an orchard during the first four years will be something less than \$3,000, including interest. This outlay will be nearly equaled by the crop of the fifth year, while a handsome profit is assured the next season.

According to a California dispatch in *The Tribune*, a small grove of Big Trees has been discovered in Placer County, on the middle fork of the American River, not far from Forest Hill. It was found by William W. Price, a botanical student in Stanford University. He thinks that this grove, of which only six trees are standing, marks the extreme northern limit of the growth of *Sequoia gigantea*. Some of the fallen trees measure twenty feet in diameter. The grove has probably been saved from complete extinction by a dense growth of Sugar Pines which surrounds it.

The identification of nearly all Grasses at any time is a difficult task for nearly every one, even for most botanists. The Grasses vary much, and in many instances they closely resemble each other. These difficulties suggested to Dr. Beal a paper, which he read before the Society for the Promotion of Agricultural Science, in Rochester, last month, entitled "How to know our common Grasses of Pasture and Lawn before they Flower." The paper was practically a key in which the distinguishing characters were laid down of seventeen of the more common Grasses, which are about all that the farmer is likely to meet in his lawn or pasture for the first month or six weeks of the growing season.

In a letter to *The World*, of this city, Mrs. Van Rensselaer states that the lawns and grass-plats about the private houses in Chicago are exquisitely neat and green, and in the great majority of cases they have not been decorated after the fashion which prevails in some eastern cities. Occasionally one sees a fine lawn defaced by gaudy pattern-beds or by groups of tall foliage-plants or by ornamental shrubs heterogeneously scattered about. But, as a rule, there is nothing but the quiet grass, or a line of trees and shrubs at the back hiding the kitchen regions and the week's wash, or else there are one or two great trees agreeably shading, without disturbing, the pretty expanse of verdure. Owners of New York areas might well go to Chicago to learn what to do to their tiny plots of grass, and owners of Newport cottages would there be just as usefully instructed in the great art of what not to do to their larger lawns.

Professor Georgeson, of the Kansas Agricultural College, writes to the *Industrialist* that he is filling a small silo with a portion of the Soy Bean crop in order to test its feeding value when so preserved. He has four varieties, two of which are so far advanced toward maturity that the leaves have begun to fall, while in the others the seeds are only half-grown. The plants were grown in rows thirty-two inches apart in loam of only fair quality, which has not been manured, and the yield of green plants is about five and one-third tons to the acre. The growth has been made in exactly three months. Its feeding value compares favorably with that of Clover and Alfalfa in nutritive qualities, and the ripe beans are only excelled by oil-meal. Cattle and hogs eat all parts of the plant greedily, and even the dry bean-straw, thrown into the yard after the beans were threshed out, was all eaten by the cattle. But, perhaps, the quality which will be most highly appreciated in Kansas is its power to withstand drought, so that not even the severe drought of last year affected it disastrously. When all these qualities become known, Professor Georgeson thinks it must take a leading place among our fodder-plants.

The strain or variety of *Solanum jasminoides*, which has been distributed under the name *Grandiflorum*, is certainly a most attractive climber for summer blooming. A plant of this, procured in the spring of last year and set in the open ground, spread over a trellis about eight feet high, and was covered with flowers when cold weather set in. In October it was cut hard back, lifted, placed in a twelve-inch pot, and kept all winter in a cool room, where it received little direct sunlight, and was sparingly watered. This spring the pot was sunk in the ground, and the vine started away with vigor. By midsummer it began to flower, and now it is more than twenty feet long, covered with large clusters of pure white flowers at the extremity of branchlets furnished with foliage of the glossiest green. It is quite as attractive in its way as *Clematis paniculata* now is, and this is paying it a high compliment. It

makes an admirable window-plant in an ordinary living-room. In Florida we have seen *Solanum jasminoides* covering a large porch and blooming luxuriantly in February. It was there called "Gloria," and it seems unfortunate that it has not an appropriate and popularly accepted name besides its clumsy scientific one.

It is feared by the importers of seeds and bulbs that the precautions against cholera may kill or keep out of the country a good many plants besides the comma bacillus. The long delays at Quarantine in the close holds of steamships will injure many seeds and bulbs and kill many living plants outright. Besides this, a delay at this season of active opening of the fall trade is most annoying, and it will cause much disturbance, if not pecuniary loss. Many invoices have not yet left the other side, and importers hardly know whether to countermand their orders or allow the stock to take the chances of quarantine delay, and what is still more dangerous, of quarantine disinfection. It may be that some of the vapors used to destroy cholera germs will not kill Holland bulbs, for example. But some of the processes in which hot steam is used to kill the comma bacillus by sheer heat would be likely to cook bulbs beyond all hope of germination. We hope the dangers of the situation are not so serious as some have feared. Importers will doubtless order shipment only from clean ports, and if health officers use proper judgment in selecting their modes of disinfection, seeds and bulbs ought to escape without injury. But it is well worth while for the importers of stock of this character to make a united effort to secure fair treatment.

There is nothing in our climate, soil or other conditions to make the hybridizing of Roses more difficult in this country than in Europe, and yet, as is well known, a great proportion of the new Roses which have proved valuable to the commercial grower and popular with amateurs have been imported. One reason for this is that there are comparatively few persons in this country who give their leisure to the cultivation and study of the queen of flowers—or of any other flower, for that matter. Why commercial growers in this country, when the sale of cut Roses is so enormous, have not given more attention to the production of new varieties is more difficult to answer. Mr. John N. May says they are too busy, but he says further that they do not hesitate to buy and try all the new varieties from Europe and pay high prices for them, although hardly one in a hundred is worth anything in this country for any purpose. Mr. May gives it as his view in *The American Florist* that if the new American Rose Society were established with sufficient capital and income to offer liberal prizes for different classes of hybrids we should soon have plenty of new Roses which would not only be good, but the best for special purposes in this country. We have already produced some good seedlings for cut flowers. Mr. Carman has been experimenting and is hopeful of getting a Rose of genuine value. Mr. Dawson has already scored some striking successes, and we have no doubt that the seeds of many good novelties are ripening now. What we should like in addition to such well-known classes as the Hybrid Teas would be a still wider range of varieties, an extension of the work already begun by experimenting with such distinct species as *Rosa rugosa*, *R. multiflora* and the Sweet-brier. *R. Wichuriana*, with its very distinct habit, is a promising subject, and, perhaps, *R. foliolosa*. Certainly our Prairie Rose, *R. setigera*, is worth crossing to gain fragrance and other good qualities, and why not some of our other hardy wild Roses? Farther south what might we not hope to obtain in the way of open-air Roses by using *R. bracteata* and the Cherokee Rose?

Elbow-room in the Country.

IT is a curious fact that the dwellers in rural towns who might easily supply themselves with plenty of land if they were willing to desert the main street, choose by preference a small lot with closely contiguous neighbors rather than strike out for themselves in a new direction. We can understand that, in the early settlement of a community, the inhabitants would naturally cluster together for companionship and protection, but when a village is fairly established it seems a pity that people should not realize how much better it is to have room to exercise their taste in cultivation, and also a place where the seclusion and privacy of a country life can be truly enjoyed. Life on the village street is less retired than in the busiest thoroughfare of a great city, for as there is not much to occupy the mind of the dwellers in small towns, the goings out and comings in of the neighbor are a matter of interest and gossip, and one can be pretty sure of a free discussion and intimate understanding of his domestic affairs by the lady over the way or behind the rear fence. Why people should submit to this, when, for the same amount of money, they might furnish themselves with ample elbow-room, is one of the puzzles which our race supplies freely for the philosopher.

When a man from the city chooses a spot a little remote from the others, he is thought to be living "in the woods" or "out in the lot," and much wonder is expressed that he should find anything in such a distant locality to make it worth his while to build there. A walk of half a mile is apt to preclude anything like "dropping in" in a village neighborhood, and really seems to shut the owner of a considerable farm out of the social current which flows up and down the main street of a village, but rarely branches off. People of limited means do not seem to value the resources and delights of country living as they deserve, nor do they readily learn to find pleasure in outdoor pursuits

nor recognize the quiet satisfactions which the thoughtful and practical can alike find in the effort to adorn and make fertile an acre or two of ground. Yet, converse with woods and fields, with shrubs and flowers, is more valuable to the spirit than village-gossip, nor need it preclude human sympathy of the broadest kind. Possibly our British brothers are right when they set the land-owner above the Philistine, and measure a man's social consequence not by his money but by his acres.

As in most social distinctions, there is some sort of instinctive basis for ranking a cultivator of his own acres above a shop-keeper, it implies a different order of faculties, a certain dignity of possession, "a stake in the country," as the English put it, so that the first impulse of a man, after he has made his shop-keeping a success, is to own a bit of his tight little island, and thereby establish a claim to some local distinction. Land is so cheap and plenty as yet in this country that we have not begun to value it as it deserves. A man appreciates the number of square feet of his possessions in a city, and by no means lacks appreciation of his ground-rents; but there ought to be a feeling for the soil of one's native land in the country quite apart from its mercantile value, so that one should start in life with an ambition to possess finally a bit of it, which would save more of our surface for the native American.

For in the Irishman is born the true passion to own a farm, which is the secret of their prosperity in the rural districts. It is astonishing to see how, with so many mouths to feed, and such limited means of feeding them, the Celt will acquire his Potato-patch, and hold on to it and add to it under the nose of his indifferent Yankee neighbor, refusing to part with it, though sorely pressed, and holding it always at a price he would never be willing to pay for it. This habit which we recognize, and laugh at good-humoredly, it would be well for Americans to acquire in time to keep some of the country for themselves. It is not enough to own a house-lot; it is a good thing to have land to cultivate for ornament if not for profit, if people have money to spend, and are at a loss for steady amusement and occupation. To such the cultivation of a garden promises a new delight—an unfailing interest; and by a garden we mean not merely shrubs and flowers, but the garden in a larger sense, as the expression of taste and artistic feeling and skillful planning, so that even the useful may contribute to the beauty of a place, and everything form an essential part of a harmonious and pleasing picture.

And we urge the acquirement of land by our people because it is a taste that grows upon one. No sooner does a man acquire one acre than he wants two; give him five, and he desires ten; a hundred, and he clamors for more, so it is well in purchasing a country-place to get enough in the beginning to make your work worth while, and to keep your lines sufficiently remote from your dwelling to avoid the discomfort of near neighbors, who sooner or later will become an oppression. For the desire for elbow-room grows upon one as he cultivates; he ever desires to add to his possessions, to extend his boundaries, to subjugate more and more of the earth to his use or pleasure, and this is a good and wholesome desire, which he does well to gratify, for, according to old Cowley, it is the garden which was God's first gift to man:

For well He knew what place would best agree
With innocence and with felicity;
And we elsewhere still seek for them in vain;
If any part of either yet remain,
If any part of either we expect,
This may our judgment in the search direct,
God the first garden made, and the first city Cain.

A CERTAIN French paper, says an editorial paragraph in a recent number of the *American Architect and Building News*, "describes a novelty which we commend to the attention of landscape-gardeners and park commissioners. There is now on exhibition in Paris, near the Trocadéro, a horticultural clock. This object consists of a bed of Alternantheras, Lobelias, Echeverias and the other proper-

ties of carpet-gardening, forming a huge disk, thirty-three feet in diameter, with the usual figures and dots of a clock-dial around the edge. On the dial move two long poles, decorated with flowers, and forming the hands of this novel clock, which keeps time with sufficient regularity. The hands are attached by a simple mechanism, sunk below the centre of the bed, and driven by a small water-motor. Where circumstances favored, we should say that an improvement on the carpet-bed dial might be made by surrounding a circular tank of aquatic plants with a sloping bank, on which the figures of the clock-dial could be made with the usual dwarf variegated plants, the whole being surrounded by a railing. It would be easy to set a box, containing the mechanism for driving the hands, in the middle of the tank, and the waste water from the motor could be utilized as the regular tank supply." These words are a surprise in a journal which usually upholds good taste in horticultural as in other matters. The guardians of our parks and the gardeners who make them need to be told that horticultural arrangements should be artistic, and not of a kind calculated to encourage a crude taste by creating showy horticultural toys which appeal to childish curiosity. These arrangements must be either of a natural sort or of a formal and palpably artificial sort, according to existing conditions. But, whatever the type, the same canons of taste which govern the proper ornamentation of a building ought to control the ornamentation of a garden or park. This fact is the one which most needs teaching—the fact that gardening is an art in as true a sense as painting, sculpture or architecture. To imitate a dial-plate with flowers and set wooden or metallic hands to moving around it by clock-work is not to design as an artist would. The arrangement which the *American Architect* commends is of the same class as the striking "floral devices" which often encumber our parks, cemeteries and the lawns of country-places. If Paris has its floral clock, Chicago has its floral sun-dial, the shadow upon which is cast by a tall inclined post composed of House-leeks. The fact that this style is common in Europe may explain its existence here but cannot excuse it.

The Woodcock Oak.

THE White Oak is one of the most familiar trees in the forests of north-eastern America, and yet we rarely see a tree of this species which has reached its full lateral expansion. The primeval Oaks of our forests grew like other forest-trees, with long, straight stems, and when the forests were cleared away, if individual trees were left standing, they showed nothing of the character which they would have had if they had grown in the open ground. At least a century is required for one of these Oaks to reach maturity, and much more than a century is needed before it attains those dimensions which mark it among our other trees as the very type of sturdiness and strength. Since the first clearings were made only an individual here and there has been allowed an opportunity to throw out its huge branches with the bold horizontal sweep which characterizes the tree in our illustration on page 450.

We have already published pictures of several famous White Oak-trees, including the Waverly Oaks, but only when we have portraits of several individuals can the full expression of the tree be apprehended. We are, therefore, glad to give an illustration of this "Woodcock Oak," as it is called, which stands about four miles east of Bedford Station, and one mile west of Bedford village, in Westchester County, New York. It is near the angle made by the Hook road and the highway between the two points mentioned above. Five feet above the ground it measures fourteen feet two inches in circumference, and two feet above the ground its girth is nearly seventeen feet. Its branches cover a circle of a hundred feet in diameter, and it is in all its proportions worthy to be classed among the notable trees of a region where fine trees are not rare.

Pine Bank.

ONE of the most beautiful spots which have been acquired by the energetic Park Commission of Boston for the refreshment of their fellow-citizens is the old estate called Pine Bank, on the border of Jamaica Pond. As the readers of GARDEN AND FOREST have already been told, the urban pleasure-ground called the Back Bay Fens, recently laid out by Mr. Olmsted, is to be connected with the Arnold Arboretum by the Riverdale Parkway, which will skirt Jamaica Pond; and several estates fronting on the pond, which is really a good-sized lake, have already been secured for this purpose. None of them is as beautiful or as peculiar in its beauty as Pine Bank, long the homestead of the Perkins family. This consists of some fourteen acres of thickly wooded ground, considerably elevated above the water-level and approached by Perkins Street. The original house was built in 1802. In 1847 it was torn down and a new one erected; this was destroyed by fire in 1869, and the present dwelling was constructed on the same site, I believe by a French architect. It is a two-story building of stone and terra-cotta, with three gables and a square projecting porch on the principal or lawn front. The carriage-drivesweeps up to the doorway on the opposite front, passing through thick growths of fine trees—Pines, Elms, Maples, Birches, Poplars and Buttonwoods. Here nature has not been conspicuously interfered with, only just enough to make the drive seem not a wild woodland road, but a fitting approach to a dignified home. Near the house are two deep, roundish, natural depressions in the ground, lovely grassy basins, which give this part of the place an individual accent, looking like little green ponds overhung with shadowy trees. On either side of the house the trees approach it nearly, and the stables are so shielded by them as not to be a disturbing element in the scene, as they too often are in small American country-places.

The other side of the grounds, fronting on the water, are still more attractive. Here the verdant surroundings are not disturbed by drive-ways or walks. The porch opens directly upon the lawn, and the smooth emerald grass extends for a considerable distance to the border of the steep high banks which overhang the pond. There are no flower-beds and no disturbing horticultural embellishments of any kind. But on either side the lawn is enframed by the thick naturally growing masses of trees, and in front the water and the opposite shore of the pond are seen through a screen of big Pine-trunks and feathery foliage, so that no more truthfully expressive name than Pine Bank could have been chosen for this delightful home. When I visited it some years ago it was uninhabited, and its effect was as of the home of some Sleeping Princess, where summer must perpetually reign, for the thick plantations absolutely shut out the noisy world behind it, and so screened the water-view that one found it hard indeed to remember that a big and busy city lay only a few miles away, and that other homes of busy modern people might be reached by a few moments' walk. Nothing more exquisitely retired and self-contained, nothing more poetically beautiful, complete and slumberous, could be imagined than Pine Bank as it then appeared; and when one recollected that the days of fairy-tales were over, and sought for an actual modern purpose to which Pine Bank might appropriately be put, it seemed as though it ought to be bought by some sentimental philanthropist and its name changed to "Honeymoon Hall," to signify that it would perpetually be preserved as a place of retirement for successive young couples unable to fly for a brief period further afield.

Now it is to be given to the people of Boston for their perpetual use, the handsome house will be preserved, and, I hope, the grounds will not be altered. Very few such charming and individual spots can exist in the neighborhood of our large towns; and this one will be invaluable as an object-lesson in the great art of treating—or of letting alone—home-grounds of an essentially woodland character. The flight of worn stone steps which leads down from the edge of the lawn to the water-side, originally belonged to the old Hancock House on Beacon Street, in Boston, and was secured by Mr. Perkins when this house was destroyed. "They are valuable as relics," writes Mr. Perkins now to the Park Commissioners, "because the most distinguished persons of colonial and revolutionary times have ascended and descended them in going to and from the hospitable door of the old mansion-house." I think they could not be put to a better use to-day than to serve the tired artisans and lively boys of Boston as an approach to the pleasure-boats which, one fancies, will be provided for their use beneath the edge of the beautiful lawn of Pine Bank.

For one, I am thankful to the Park Commissioners of Bos-

ton for bringing this beautiful place to general attention, and for the opportunity to praise its beauty, and to say that the one visit to Pine Bank remains among the fairest of those pictures which every traveler preserves in a special little inner mental gallery, apart from thousands of others which, despite greater magnificence or more striking associations, are nevertheless not his best and dearest. If I tried to count over a dozen scenes which had most poetically spoken to my imagination as well as delighted my eyes, one among them would surely be the picture of Pine Bank on a hot summer afternoon when the sunlight slanted through the Pines, touching to green-gold the grass which looked as though no foot heavier than a fairy princess's had trodden it for years, and turning the pretty sheet of water beyond the screen of whispering Pines into a stainless azure mirror. Good days have, indeed, dawned for the people of our large towns when such spots as this are secured for their perpetual pleasuring.

Native Shrubs of California.—VIII.

OF the *Ceanothus* genus, or California Lilacs, as they are not inaptly called, there is so great a variety on all our hills and mountains that one scarcely knows with which to begin the account. They are a large part of that almost impenetrably dense brushwood, called "chaparral," which covers middle elevations of the Coast-range, forming a distinct belt between the herbaceous vegetation of the foot-hills and the forest-growth on the highest ridges and summits. Another series of species, distinct from those of the Coast-range, inhabit the Sierra Nevada, and are more commonly interspersed among the forests, or along the borders, mingling with other woody growths.

Among the Coast-range species, *C. thyrsiflorus* holds a conspicuous place in point of ornamental qualities. Though often flowering profusely as a shrub six or eight feet high, under favorable conditions it matures into a shapely tree twenty-five feet or more in height. In habit it is compact as the Lilac, with green-barked branches and twigs, and a deep, glossy three-ribbed foliage. It is strictly evergreen and flowers more or less freely from March to May, the color of the large, dense clusters being a perfect blue. In any collection of ornamental shrubs it should hold a welcome place. Twenty years ago it was no rarity upon the lawns and shrubberies in the northern parts of San Francisco, where it had been spared when other and less attractive native growths had been cleared away for the establishment of homes. This species is not found away from the seaboard, nor has it an extensive range along the coast. It is, I believe, hardy in England, where it has been much admired, though in that climate it is not well at home, if we may judge from Lindley's figure in the *Botanical Register* (vol. xxx., t. 38), in which it appears with a comparatively pale foliage and lax clusters of light blue flowers, altogether of inferior beauty compared with the shrub on its native hills.

On the flanks of Mount Tamalpais, and in many like situations among the Coast-range hills, grows *C. sorediatus*, very unlike *C. thyrsiflorus* in habit, and displaying a greater profusion of bloom in very small clusters. Although its branches and branchlets are short, stiff, and even somewhat spinose, they have a curving tendency which gives to the bush, in a mass, a rounded, rather than angular outline, and the whole surface of a well-grown specimen in full flower appears like a billowy mass of sky-blue, the flower-clusters, though small and short-stalked, decking every twig. Many years ago some small plants were transferred from the adjacent hills to the university grounds at Berkeley, where they have ever since been subjected to an annual clipping by the workmen on the grounds, and reduced to solid hemispherical or conical outlines. These plants have suffered little by this unkindly treatment, and each spring, for weeks together, they are like leafless cones of blue, the flowers quite concealing the foliage. This hardy native is one of the best shrubs for edging purposes, whether desired for usefulness or ornamentation. Like *C. thyrsiflorus*, it is evergreen, the foliage small and of rounded outline.

Every one who has journeyed to any part of the Sierra Nevada in early summer has admired *C. integerrimus*. This is a large shrub of loose and open growth, with thin sea-green foliage and very conspicuous long-stalked clusters of flowers, prevailing white, though occasionally pale blue. It has not the merit of perennial verdure, the foliage being mainly deciduous, and for this reason, although it is perhaps the most beautiful of all *Ceanothus* when in full bloom, it is not particularly attractive at other seasons. The Coast-range counterpart of this species is the somewhat rare *C. Andersonii*, with more abundant foliage than *C. integerrimus*. The leaves are smaller

and the panicles of white flowers at least equally conspicuous and more profuse. It has been found only in the neighborhood of Santa Cruz, but the botany of the mountains southward is yet scarcely explored, and *C. Andersonii* is in all probability established there. In the Santa Barbara region of the Coast-range is *C. spinosus*, another exceedingly handsome species of the larger and arborescent class. This has glossy evergreen leaves of small size, and ample clusters of light or deep blue flowers. It takes its specific name from the fact that many of the branches end in sharp, leafless, spur-like, or, rather, thorn-like points. Across the channel from Santa Barbara, on the large island of Santa Cruz and one or two neighboring islets, is found a peculiar *Ceanothus*, extremely unlike any mainland species, and the largest member of the genus. It was discovered by the writer in 1886, and named *C. arboreus*, in reference to its great size, clean tree-like trunk and well-rounded head. Its broad and ample foliage is white underneath, and the flower-clusters white or pale blue. In Professor Sargent's *Silva of North America* this is figured as a variety of *C. velutinus*, to which it seems to me to be as little related as to any species of the genus. It has one close ally, however, in a Mexican species, *C. azureus*. This has a more elongated and relatively narrow foliage, but the same texture, pubescence and whiteness beneath. It is an interesting fact that all the discoverable connections of the novel and interesting flora of the islands off Santa Barbara are with Mexico rather than with California. Upon the mainland mountains behind Santa Barbara is another *Ceanothus* of arborescent growth, in habit like a Wild Plum-tree. In late February its head is a mass of white bloom, so great is the profusion of small clusters of flowers on every branch and twig. This is *C. megacarpus*, a sort so rare as to have been but seldom seen even by a botanist. It may, perhaps, not be infrequent along the higher summits of mountains in the unexplored districts of southern California.

Among shrubby species of *Ceanothus* is the surpassingly pretty *C. foliosus*, with very small crisped or almost curled foliage of the darkest green, which is half-hidden at flowering-time under the many small, roundish stalked clusters of indigo-blue. It is only a foot or two in height, but with countless widespread branches, so that it forms a dense low thicket, almost completely covering the mountain-slopes in its own peculiar region, the foot-hills of Mt. St. Helena of the inner Coast-range. At the lowest elevations, just bordering the Napa valley, in the same general district, we have a somewhat closely related, but large and graceful, blue-flowered sort in *C. Parryi*, the original specimens of which were obtained by Dr. Parry from the shrubbery in front of a vineyardist's residence, whose good taste had left to them their foothold on the soil when other bushes had been cleared away. It is quite common in that region.

It is not possible, in a short account, to make special mention of more than one in ten of the entire list of Californian *Ceanothus*, though almost all are beautiful. But I am unwilling to conclude without speaking of two of the humbler sorts which adorn each its own place in the woods of the Sierra Nevada. In the heart of the great Pine district of the middle Sierra, a slender, low, half-trailing species, *C. diversifolius*, is singular in that it covers the ground throughout extensive open forests with a perennial verdure; and this is saying much for any plant in the middle mountains, where the forests in the main have no undergrowth which is not as short-lived as the rainy season of the year, and when all through the months of summer and autumn everything under the Pines and Redwoods is as brown and sere as upon the open plains below. *C. diversifolius*, wrongly called *C. decumbens* in older books, is semi-herbaceous, with broad, thin, soft foliage, and in all but its trailing habit and blue flowers is much like the familiar eastern species, *C. Americanus*. *C. Americanus*, by the way, as it now blooms in our university garden, is apparently quite at home on this side of the continent, and no white-flowered Californian species is prettier. In the Sierra, at higher elevations than are reached by *C. diversifolius*, grows a stout, prostrate, densely matted *Ceanothus*, with evergreen, prickly foliage and rather inconspicuous blue flowers, forming usually a close carpet under the trees. The school-children in mountain districts call it Squaw Mats, or Mahala Mats, the old Hebrew name Mahala having become for some reason the popular designation of the feminine membership of the Digger Indian tribe. The shrub is evergreen and very hardy, as well as compact and low, and has been spoken of as possibly useful for hiding the summer brown of unirrigated knolls and slopes in parks and other places along the seaboard. No experiments that I know of have been made. But, as the home of this unique *Ceanothus* (*C. prostratus*) is on the

shaded and cool elevations of elevated parts of the Sierra, I doubt if it would succeed on exposed places in a climate so different as that of the Coast-hills and plains.

University of California.

Edward L. Greene.

The Polemoniaceæ of the Lake Region.

NINE species belonging to the Polemonium family are indigenous to the region of the great lakes. They represent two genera, Phlox and Polemonium. Besides these, *Gilia coronopifolia*, the standing Cypress of the garden, a native of the southern states, is reported as an escape from cultivation on the north shore of Lake Erie. These are all that I can ascertain as included within the limits, though one or two species of Phlox may be found within the southern border.

Taking the Phloxes about as they flower, the first to appear in the region of the upper lakes is *Phlox bifida*, or Beck's *Lychnidia*. It is apparently confined to Illinois and the western part of Indiana. It comes into the lake region at the head of Lake Michigan, being found in the narrow belt of sandy land which encircles it. Here it is not uncommon in open, grassy places in the woods, or along their margins. I have never seen it at any distance from the woods, though it is called a plant of the prairie. It likes a dry soil, where the most common plants of the season associated with it are *Ranunculus fascicularis*, *Viola pedata*, *Oxalis violacea* and *Claytonia virginica*. It comes into bloom near the end of April, and lasts till the early part of June. *Phlox bifida* is of a diffuse and prostrate habit, the main stem frequently half-hardy and persisting through the winter under a covering of dried grass and leaves. Hence the plants may be disfigured at the time of flowering by the partially dead leaves of the preceding year. The stems are from three to eight or ten inches long, provided with several erect or ascending branches, three or four inches high. The pale purple or white flowers are so abundant as to largely conceal the foliage and cover the ground when growing close together with a carpet of bloom. The lobes of the corolla are wedge-shaped, each deeply cleft into two oblong divisions, giving to the limb a ten-rayed outline. At the base of each lobe are usually two more deeply colored blue or purple spots, sometimes uniting to form a ring with a raised point for each segment, forming a pretty eye to the flower. The slender tube is quite uniform in color, of a bluish purple tinge. But the limb varies considerably, from white to various shades of purple. Those found near Chicago are prevailingly white, at least when the flowers open, though they may become colored with age, or when picked and placed in a vase change to purple or even to blue.

P. bifida is a western representative of the better-known and much more widely distributed *P. subulata*, or Moss Pink, of localities east and south. The western limit of the Moss Pink is in Indiana, where it comes into the neighborhood of *P. bifida* in the vicinity of Lafayette. In the lake region it extends from western New York, through Ontario, to southern Michigan. It is also a plant of dry locations, generally growing in sandy or rocky soil. Being an evergreen, the creeping and matted stems and assurgent branches have a brighter look than those of *P. bifida*. The segments of the corolla are obcordate, or slightly notched, but are sometimes entire, and the flowers lack the radiate appearance seen in those of *P. bifida*. They are about as variable in color, the wild forms showing pink, pale rose, purple and white shades, usually with a darker centre. The depressed mats and cushions of plants are covered with flowers in May and June, and enliven many stretches of sand or chert or thinly coated rock with beautiful splashes of color.

The earliest of the taller Phloxes is *P. divaricata*. It starts a little later than the two preceding, its period of inflorescence being mostly limited to May and early June. Then the damp rich woodlands where it grows are bright with the large and fragrant flowers, often massed in extensive beds. It is a profuse bloomer, displaying from ten to twenty flowers at once in its showy, corymbose cymes. The stems are from one to two feet high, the lower part smooth and often colored with purple; the upper part, with the peduncles and calyx of the flowers, is glandular pubescent. The leaves are but slightly glandular, becoming smooth and somewhat glossy with age. After the flowers are gone, and especially in the early fall when the floral stems have disappeared, the barren, summer shoots springing from the root are a pleasing feature to be met with in the shady woods. Then these prostrate stems, bearing rather short, sessile, ovate leaves somewhat whorled at their ends, and with a shining half-evergreen look, strikingly resemble those of the pretty Fringed Polygala, and may be mistaken for that plant.

The flowers of *P. divaricata* are among the largest in the genus, being from an inch to an inch and a half across. Many shades occur, prevailingly those with a bluish tinge. The most common are bluish purple, purple, pale or deep lilac, pink, white, or white tinged with blue or pink. The large flowers, their delicious odor, and the deep green of the shapely leaves, make this one of the most charming of the wild Phloxes. It is the most widely spread of any in the Lake region, extending throughout except in the extreme northern part. It goes as far east as Qwebe, the most easterly range of any of the native Phloxes. South of this region it is very common.

P. pilosa is found from the head of Lake Erie to the Saskatchewan, and south-eastward to the Gulf of Mexico and the Atlantic. It accommodates itself to a wider range of soil and other conditions than the rest of the Phloxes of the region—from quite dry sand to the damp, rich soil of the prairie. It is the only Phlox common in the Pine Barrens. It is a denizen of the meadow, the copse and the open wood. The flowers appear a little later than those of *P. divaricata*, and continue till the middle of July or even later. The whole plant is hairy, the upper part, especially the branches and pedicels of the broad cymes, very glandular-pubescent, so that light bodies adhere to them, and small insects are held fast, as in species of *Silene* and *Pentstemon*. The linear, or lanceolate, leaves are very sharp-pointed. The corolla lobes are from round-obovate to oblong, and each is marked at the base with brownish purple spots, forming a handsome eye. The predominating colors are red, but white is not at all rare. The present year the white flowers were in excess at the opening of the season, the brighter ones coming in later. This may have been due to the unusual number of cloudy and rainy days, since the phenomenon was exceptional, and the colored kinds suddenly replaced the white ones when the days became warm and sunny. The most common floral tints are rose, bright pink to nearly red, rose-purple, pale blue and lilac, all shading into one another and into white, in almost endless variety. When the plants are massed in spots scattered about in the damp prairie, sometimes so thickly covering the ground that little else is seen, and in areas to be measured by the acre, they furnish the eye with the richest glow of color, and in brightness verify the fitness of the name, Phlox, which means a flame.

From the latter part of June well on into August *P. glaberrima* is the most common Phlox of the prairies or the open woods and their sunny borders; usually in moist grassy localities, or where there is enough of sunlight for grass to grow freely. It is essentially a prairie or meadow Phlox. The plants are very smooth, and of a pale but glossy green. They are from one to four feet high. The slender stems, stretching up among the grass, lift the bunches of flowers, from three to six or eight inches long, well into the sunlight. The leaves are long and very narrow, and the pairs are so far apart upon the stem as to give it a naked look. The plants are often massed in extensive beds, but their pink flowers are less striking than those of *P. pilosa*. The lobes of the corolla are quite uniformly roundish, and the flowers in form and size are more nearly like those of *P. Drummondii* than in most of our wild species, but lack their richness of color. There is often a deeper-colored pink or reddish line traced upon each lobe, a five-rayed star on a paler ground, or the lobes may have a white or pale base pervaded by a red crenellated line.

Two of the panicled Phloxes are represented in the lake flora—*P. paniculata* and *P. maculata*. They are mainly southern in their range, coming into the lake-region south of Lake Erie and Lake Michigan. *P. maculata* is native as far north as southern Minnesota. As both are often cultivated they readily escape, and may be more widely spread in consequence. The wild plants are sparsely found in northern Illinois in rich woods and by the shaded banks of streams.

Polemonium is represented by one species, *P. reptans*, the Greek Valerian, often cultivated. It is found from western New York to central Minnesota and southward. It is most plentiful in the rich open woods and along their borders, as it does not like dense shade. Some of the finest plants may be seen in clearings, where it flourishes among the litter, or are found persisting by the fence-rows lined with brambles and Hazel. The diffuse stems, ten to twenty inches long, with several often rising from a single root, and the pinnate leaves, with their three to ten pairs of ovate or oblong leaflets, form handsome clumps of lively green. When richly furnished with flowers in May and June, few plants of the woods are more attractive. The short tube and flaring limb make the flowers somewhat bell-shaped, and from this, with the color, they are generally known as Bluebells by country people. They have a light blue color, varying toward lilac, either sky-blue, or more often that peculiar restful shade which the French

have named bleu d'œil, eye-blue. White flowers are also found.

All of these plants are easy to cultivate, and, if not already in the garden, deserve a place there. Trials with *Phlox pilosa* show that the flowers increase in size and number, and in richness of color, when transferred to a garden-soil. The wide range of soil and exposure to which it adapts itself in its natural condition is also greatly in its favor. They are mostly plants of the open field, delighting in the full sunlight, though some, like *P. divaricata* and the Greek Valerian, need or do best in partial shade, the former bearing that which is quite dense. Since all spontaneously bear white flowers, the range of color between white and the red and cyanic series show the possibilities of variation in the hands of the skillful gardener. This has not only been demonstrated in the Texan annual, *Phlox Drummondii*, whose beauty and endlessly varied colors all admire for a bedding-plant, but is shown in the northern perennial, *P. paniculata*, and its variety or synonym, *P. decussata* or *acuminata*, and the crosses between these and *P. pyramidalis*, which the best authorities identify with *P. maculata*.

Englewood, Chicago, Ill.

E. J. Hill.

Foreign Correspondence.

London Letter.

THE exhibitions and conferences at the Royal Horticultural Gardens at Chiswick on Begonias, hardy Ferns, Apricots and Plums, were succeeded by a large and important exhibition of high-class fruit at the so-called International Horticultural Exhibition at Earl's Court, where a horticultural display, strangely enough, was united with the "Buffalo Bill" show.

An exhibition such as that at Chiswick, with the remarkable gathering of Begonias and Ferns, could hardly be seen anywhere but in London. An enormous collection of species of cultivated Begonias came from Kew, with splendid productions from the two great Begonia raisers, Messrs. Laing and Messrs. Cannell. Probably never before have so many species, well grown and correctly named, been seen at one exhibition. But, interesting as this collection of species was, attention was centred in the small group of species which constituted the primitive forms. From these have been created, with phenomenal rapidity, the splendid races of double and single tuberous Begonias, perhaps, at the present day, the most popular class of greenhouse-plants in this country. Mr. Veitch, in an able address embodying the more salient points in the history of florists' Begonias, gave an account of how the race had its origin in the now neglected *B. Boliviensis*, a species of graceful growth and brilliant flower color, and the small *B. Pearcei*, with bright yellow flowers and exquisitely mottled foliage. From South America came *B. Veitchi* and *B. rosæflora*, which were immediately seized upon by hybridists, and the intercrossing continued until the features of the original parents became so blended that now it is a difficult matter to trace the peculiar characteristics of the primitive species. The contrast between these and the finest productions of Laing and Cannell fully justified the remark that the Begonias of to-day are among the most conspicuous triumphs of English floriculture. And this triumph is peculiarly English, for no foreigner took an active part in its production during the early experiments. The exhibits of Cannell and Laing, who both had marvelous displays of flowers and plants, showed the florists' Begonia up to date, for they both had their latest seedlings in doubles and singles. It is probable that the range of possible tints in Begonias has been exhausted, but Mr. Laing is sanguine of extending the gamut of hues by persistent crossing, and he hopes, moreover, to get a strain with variety of petal markings. He has already Picotee-edged single varieties, and one specimen at Chiswick had broad pure white petals broadly edged with carmine, a most striking variety. While many think that the Begonia is not improved in being cultivated into "six-inch singles" and "Hollyhock doubles," as long as the public admire them and buy them the florists will continue to supply these novelties.

What is now wanted is a new species that will blend with the present race of hybrids and add to it new characters, and such a desideratum may be expected among the new discoveries in Africa and other unexplored regions. When, a few years ago, the island of Socotra yielded its solitary Begonia through Professor Balfour to the English florist, it was immediately put to use in hybridizing, the result being a race of very pretty varieties, especially valuable, as they flower through the winter, those named John Heal and Winter Gem being among the first raised. The fine-foliaged Begonias have of late years had more attention paid to them, and the Continental hybridists have produced some distinct and handsome kinds, such as Arthur Malet. There is an astonishing range of variation in the Begonias of the Rex or fine-foliage type, and in all probability we may see soon the gorgeous flowers of the tuberous section combined with ornamental leafage. Nor has the fibrous-rooted section of the genus, which comprises the bulk of the species, been worked upon much, and some good things may come from their influence. Mr. Watson told us, in introducing the paper he had prepared on the cultivated species, that there are about 400 species of Begonia known, and about half the number are in cultivation at Kew, a large proportion of them being shown on this occasion.

The gathering of highly cultivated specimens of hardy Ferns has seldom, if ever, been surpassed in excellence at a London show, and this was mainly brought about by the well-known hardy Fern specialist, Mr. E. J. Lowe, who was instrumental in bringing the unique collection from the Clifton Zoological Gardens, many of the plants in which were in huge pots, and the plants measuring a yard or more across. I had never before seen such a fine collection, and never before realized the fact that the finest forms of hardy British Ferns are in no respect inferior to tropical kinds we admire in hot-houses. Some, indeed, are equal in elegance and texture of frond to the Todeas, among Filmy Ferns, and others, such as the variety of *Polypodium vulgare* called *Trichomanoides*, as fine as some of the *Trichomanes* and *Hymenophyllums*, apart from their transparency. The wonderful amount of variety among the forms of *Scolopendrium vulgare* (Hart's-tongue), *Lastræa filix-mas* (Male Fern) and *Athyrium filix-fœmina* (Lady Fern) seemed to surprise all who were not specialists in hardy Ferns. The collecting of these varieties has been done for the most part by amateurs in a very quiet way, particularly in the western counties, so that Londoners have not had an opportunity of seeing what a wealth of beauty there is in hardy Ferns. I can see that it is quite possible to have in an unheated fernery all the beauty of form possible in a tropical fernery, not even excepting the delicate Maiden-hair Ferns, for the forms of *Adiantum Capillus-veneris* are quite as beautiful as the tropical kinds, while miniature Tree Ferns may be made of some forms of *Lastræa*, as some specimens with clear stems of a foot or more were shown on this occasion.

The late-flowering trees and shrubs, of which we have far too few, now begin to give glints of color to the arboretum, and at Kew the old trees of *Sophora Japonica* are snowy with bloom, as is also *Catalpa bignonioides*, which, though it flowers well on the dry gravelly soil, is not nearly so fine as further down the Thames valley. In the neighborhood of Pope's Villa at Twickenham there are some magnificent groups of the tree in full bloom, their great branches leaning over and almost touching the water. Some of the trees are forty feet high, and have as fine heads as any I have seen in southern Europe. *C. speciosa* is becoming widely distributed, but as yet our tree-planters are not as familiar with its merits as you are in America.

The *Paulownia imperialis* is not a tree for general planting in England, except, perhaps, along the south coast; but I saw the other day some fine effects obtained by treating it as a "sub-tropical" plant, as is sometimes done in America; the foliage of the strong young shoots was very

massive, and associated with other fine-leaved plants such as *Cannas* and *Ricinus*. The plants are cut down every autumn, and in spring they send up vigorous shoots, which are thinned out to three or four, and furnish a mass of immense leaves all summer. To see the *Paulownia* to perfection in Europe one must go to the sunny south, and I have a pleasing recollection while writing this of the magnificent avenues I saw of it in full flower at the end of April in the gardens of the Villa Borghese and the Pincian Hill at Rome, where the climate exactly suits it. Among other interesting things in the arboretum are the *Ceanothuses*, the French hybrid varieties of *C. azureus*, of which there are several in nurseries, but none so fine as the oldest

large as *L. purpurata*, with broad (not reflexing) sepals of pure white, and a lip painted with brilliant tints of purple and crimson. Messrs. Sander also had fine examples of autumn-flowering Orchids, and especially of that noblest of all *Vandas*, *V. Sanderiana*, which seems to have dropped out of notice until lately it has been shown splendidly from St. Albans. It would be interesting to find out (if it were possible) how many plants of the original importation of *V. Sanderiana* are alive now. The hundreds, and perhaps thousands, that were distributed to all parts, not a few to your American collections, would surely have been more in evidence at exhibitions than they have been if it flourished as most growers thought it would. In addition

Fig. 74.—White Oak, near Bedford, Westchester County, New York.—See page 446.

Gloire des Versailles, with its pale purple-blue plumes of flowers. The finest dwarf autumn shrub is the new *Hypericum Moserianum*, a cross between *H. calycinum* and *H. patulum*, between which species the hybrid is exactly intermediate. It has large shallow flowers of bright yellow, with tufts of crimson-lipped stamens. It flowers profusely and continuously, and, in short, is quite a gem among hardy flowering shrubs. The florists, too, have found out that it forces well, and can be had in bloom early in the spring, so that will tend to popularize it more.

At the Earl's Court Exhibition a fine Orchid from the St. Albans Nurseries was *Lælia Gravesiæ*, a hybrid between *L. crispa* and *L. purpurata*. It is an exquisite flower, as

to the cream of the autumn-blooming Orchids, Messrs. Williams, of Holloway, had some new plants and Orchids, the latter including the rare little *Pachystoma Thompsonianum*, which received a first-class certificate, though it has been in gardens for years. The new plants included among *Dracænas*, *D. indivisa Veitchi variegata*, a cumbrous name for an elegant plant with narrow leaves striped with yellow, and which will, no doubt, be a popular decorative plant in course of time. Other new *Dracænas* of the ordinary reddish-leaved type were Miss Glendinning, Mrs. Laird, H. E. Milner and A. Laing, to which first-class certificates of merit were awarded. *Carludovica palmæfolia* and *Cupania elegantissima* were two elegant plants for decora-

tive use in Messrs. Williams' group. The great floral feature of the show, however, was the Begonia trophy of Messrs. Laing, who quite surpassed themselves. Never before at any show has such a marvelous array of double and single Begonias been seen. They were arranged in a rising bank with a background of Palms and other foliage, and disposed in groups of one color a yard or so square; the effect was brilliant in the extreme. The colors ranged from pure white through pale and deep yellows and warm orange up to the most intense scarlets and crimsons. The gold medal won by the exhibitors was highly merited.

Cultural Department.

The Self-pollination of the Grape.

THE Grape has small greenish blossoms which open in a peculiar and interesting way, and protect the stigmas from outside pollen till they have opportunity to become self-fertilized. The petals form a kind of cap which covers the sexual organs. When the flower opens the petals break away from their attachment at the base, but remain fastened to each other at the top, thus keeping the stigma and anthers covered. Finally the petals curve outward from the base and upward, and the expansion of the stamens usually dislodges the cap. In the nearly related genera, *Cissus* and *Ampelopsis*, the petals open at the top and expand in the usual way. The calyx in all *Vitaceæ* is practically obsolete, and plays no part in the opening of the flower.

An opening bud is shown in Figure 75; *a* being a petal just detached at the base, and curved outward, disclosing a portion of a filament (*b*), and the outline of a part of the pistil. Figure 76 shows the pistil with the cap removed, and illustrates the expansion of the different forms of stamens. If the flower has short filaments, as at *a*, they become reclined (*b*), or recurved (*c*). If the flower has long filaments (*d*) they become erect, as at *e*. This structure of the Grape-flower is of practical interest to the grower, and we are glad to give a study of the subject in a paper read before the American Association for the Advancement of Science at its meeting in Rochester last month by Professor S. A. Beach, of the New York State Experiment Station.

The best time for examining Grape-buds, to find out whether self-pollination takes place before the flower opens, is just at the time when dehiscence of the corolla begins. Dehiscence usually begins at the base of one of the petals, and extends upward half or two-thirds of its length. Afterward the straightening up of the stamens, if they have long filaments, or the reclining or recurving of the stamens, if they have short filaments, dislodges the calyx, or cap, as it is frequently called, and carries it upward and to one side, thus uncovering the

dehiscence of the corolla allows the moisture to escape from the open anthers, and the pollen, becoming dry, is discharged abundantly on the pistil before the cap is displaced, thus insuring self-pollination before the stigma is exposed to foreign pollen.

Fig. 77.—Two clusters of the Lindley Grape from the same vine, with abortive fruits showing lack of proper pollination.

In every instance when buds could be found in the right stage of development it was observed that self-pollination occurred before the blossoms opened. The total number of individuals in which self-pollination was thus observed is seventy-seven, distributed among eight species and their hybrids and crosses. Several other varieties were examined without being able to demonstrate that self-fertilization occurs before the blossoms open, but in no case was this true when buds could be found at the proper stage of development above noted, namely, just beginning dehiscence.

Clusters of grapes were inclosed in paper bags before the blossoms opened and were allowed to remain covered until the blossoming period had passed. This effectually shut out foreign pollen and made it possible for the stigmas to be pollinized only by pollen from stamens of the same flower or of the same cluster. Some results of these tests may be briefly summarized as follows:

Of four cultural varieties having pure *Labrusca* blood, three were found to be fully self-fertile, and the fourth nearly so. Their stamens in every case are borne on long filaments and self-pollination occurs before the blossoms open.

Of seventeen hybrids of *Vitis labrusca* and *V. vinifera*, three were fully self-fertile. These have long filaments. Whether self-pollination occurred before the blossoms opened was not noted. Another one, though not fully self-fertile, still developed a large per cent. of the ovaries into perfect fruit. It has long filaments. Self-pollination occurs before its blossoms open. Eleven proved to have pollen self-irritant only—that is, the ovaries started to develop and soon fell away or persisted as abortive fruits. Ten of these have short filaments. The character of filaments of the eleventh one was not noted. Self-pollination was observed with seven of this class. Whether it occurs with the other four cannot be stated. One proved to have pollen impotent—that is, the ovaries were not incited to any perceptible growth. It has short filaments and self-pollination occurs before the blossoms open.

One cross of *V. labrusca* having *vinifera* blood was found

Fig. 75.—The Opening Bud of a Grape-flower.

Fig. 76.—Pistil and Stamens of a Grape-flower.

stigma. Occasionally the filaments fail to perform this work, and the cap persists for an indefinite period, as a withered covering on the apex of the young fruit.

The anthers are already opened when dehiscence begins, but the pollen has not yet been discharged from them. The de-

to have pollen self-irritant only. It has short filaments. With this cross and the seventeen hybrids of *V. labrusca* and *V. vinifera* above noted, none but those varieties having long filaments can develop fruit when self-fertilized only. In every instance the vines with short filaments were really pistillate since they failed to develop fruit when self-fertilized only. According to Munson this is commonly true of wild bearing vines of all species of *Vitis*. A specimen of *V. æstivalis* transplanted to the vineyard has long filaments and proves to be fully self-fertile.

The Delaware, classed doubtfully as a hybrid of *V. vinifera* and *V. riparia*, has long filaments and is fully self-fertile.

Vitis Doaniana, as represented by a specimen transplanted to the vineyard, has pollen self-irritant only, and self-fertilization occurs before the flower opens, but fails to produce fruit.

Pollen that is self-impotent or self-irritant only may prove potent on other varieties. This was found to be true with two of the seventeen hybrids of *V. labrusca* and *V. vinifera* above noted.

These experiments show that under the conditions of soil and climate found at Geneva, New York, any one of the following list of grapes will probably prove unfruitful when planted by themselves out of the reach of pollen from other varieties: Massasoit (Rogers No. 3), Wilder (Rogers No. 4), Rogers No. 5, Gaertner (Rogers No. 14), Merrimack (Rogers No. 19), Requa (Rogers No. 28), Aminia (Rogers No. 39), Essex (Rogers No. 41), Barry (Rogers No. 43), Herbert (Rogers No. 44), Salem (Rogers No. 53), Black Eagle, Eumelan and Brighton.

The following hybrids are able to fruit without the aid of pollen from other varieties: Rogers No. 13, Agawam (Rogers No. 15), Rogers No. 24, Rogers No. 32 and Delaware.

Notes on Begonias.

BEGONIA *Boliviensis* Madelaine is one of the new plants of the season introduced by a French house. This varies from the type only in having flowers of a different shade of red, they being dull carmine or bluish red, while those of the original plants are a light vermilion. They are of the same thin texture as the type. *B. Boliviensis* is probably little grown now, but it is a very attractive species with its *Fuchsia*-like habit. As one of the first introductions of tuberous *Begonia* and one of the parents of the first hybrid *Begonia*, it has always been an interesting plant to fanciers aside from its beauty. From this species the first of the double-flowering hybrids were produced, and growers of these plants from seed will often find among the seedlings many showing a trace of *B. Boliviensis* in the long narrow leaves and long lax peduncles. It is only a few years since that the majority of the plants from seed of double kinds supplied by the leading growers, were largely only variations of this type. The present race of hybrids, however, has reached a stage where little trace of *B. Boliviensis* can be found. The flowers are now wide open, round or nearly so, the plants dwarf and the flower-stems perfectly rigid. While it is pleasant to follow flower fashions, it is sometimes pleasant also to retain plants which have a distinct character different from those in special vogue, and *B. Boliviensis* is one of the most distinct and graceful of the family.

Begonia pictavensis is a hybrid between *B. Scharffiana* and *B. metallica*. It proves to be a strong-growing plant of not very much character in the foliage, which resembles mostly that of *B. metallica* without its dark veinings, which are so attractive, and they are of thicker substance without the richness of those of *B. Scharffiana*. The flowers are large and pure white, studded on the reverse of the petals with numerous rosy hairs of a beautiful hue. A cluster of these is very attractive, and they give value to a plant otherwise not especially a great gain. It will be seen that the flowers, while not so large, are of the character of those of *B. Scharffiana*, and they open more freely than those of this variety, though under some conditions *B. Scharffiana* is very free and does not maintain its reputation as a producer of imperfect flowers. *B. pictavensis* is also known as *B. Credneri*.

Begonia Vernon (*B. semperflorens atropurpurea*) has proven to be a very satisfactory bedding-plant during a specially hot, dry season. It is always in flower, and these are perfectly weather-proof, rains having no effect with them. The leaves have not scorched under the blazing sun. The purplish tinge in these is very variable, increasing and diminishing during the season, but always giving a rich and distinct effect in masses. As this is a plant quickly propagated it is likely to grow in favor where low-growing neat bedding-plants are useful.

Cape Oxalis.—II.

THE prevalent idea is that the *Oxalis* is a trifoliate plant, having foliage much resembling that of the White Clover, and some of the early botanists named it *Trifolium*, being acquainted only with the three-leaved kinds, such as *O. acetosella* and *O. stricta*, found in the greater part of Europe and America. The species of which I mean to speak are of a very different appearance as, in place of being nearly or quite stemless, they have stems a foot or more in length, along which the small leaves are scattered, the whole plant having, indeed, much the appearance of a Cranberry-plant.

How many of these are distinct species I shall not attempt to say, but as garden-plants there is a considerable diversity of appearance. The bulbs of all of this section are of a light salmon-color, broad at the base and sharp-pointed at the other end. They are usually sold of a size too small to flower well. A good bulb of *O. hirta* or *O. rosacea* should be as large as a small Tulip-bulb. These species generally flower very freely for a considerable time and then cease altogether, but they are not unornamental when out of bloom if placed among other plants where their drooping habit gives variety. All of them produce bulbs freely at the root and may also be propagated by cuttings. *O. macrostylus* is a species with rather dull purple flowers, three-fourths of an inch across, but with rather narrow petals. It is not very desirable, since there are many brighter kinds. A bulb of this variety should be as large as a filbert. The stems are generally not more than nine inches long. The flower of *O. hirta* is bright red, not bluish purple as in Jacquin's figure, which seems to have faded in the course of the century which has elapsed since it was printed. This is quite commonly offered in the catalogues yet, and is a very desirable kind, though the bulbs furnished are almost always too small. *O. hirtella* is much like *O. hirta* in all respects. The color is somewhat purplish, however.

Oxalis multiflora is well named, for its blossoms are more numerous than in any other species of this section. They are about three-fourths of an inch across, of a lilac color with yellow throat, and are borne upon long side-shoots emitted from the main stem from nearly every axil, so that the plant has a thick, bushy appearance. I recommend this as an excellent pot-plant. *O. rubella* is also very good; its flower is brighter than that of any other variety, except *O. fulgida*, which is somewhat less floriferous though more brilliant.

Oxalis rosacea has the largest flowers and the largest bulbs of the section, the former being frequently two inches in diameter, light purple with yellow tube. Both in size and in color they are much unlike Jacquin's figure. The only other species of this section which I have grown is *O. canescens*, which is of smaller growth than most of the others, and produces rather small lilac flowers very profusely and is a very good kind for pot-culture.

Kämpfer's Iris.

THIS Iris is more correctly called *Iris lævigata*, but is better known as *I. Kämpferi* in gardens of to-day. These plants seem, in common with many other gems from Japan, specially adapted to American gardens. They like the sun, cold does not hurt them, and their only enemy is the rose-bug, which infests the plant during the blossoming-season. It is surprising that these Irises are not more common in gardens, since failure is possible only when the roots have not been supplied with sufficient moisture, and, indeed, they may be grown successfully as sub-aquatic plants, for if covered with ice through the winter they come out in the spring all the stronger for their stern discipline. They like best mud or a rich black soil, though they can be made to grow in the poorest soil if plentifully supplied with moisture through the summer months. They are at their best in July. There are no flowers in the hardy flower-garden through the whole season which surpass them in beauty, and it is probably to this fact that they owe their popular name of Poor Man's Orchids. The best time to plant the Japan Irises is in the fall. When the foliage begins to turn yellow they may be divided and reset. Care must be taken to give them rich soil, as they are permanent plants, and need lifting only when the clumps get too large and are starved by remaining too long in one place. The best way to divide them is to lift carefully, and use the spading-fork to separate, not cut, the plants asunder. Treated in this way they will grow stronger and flower more freely the next season. These Irises may also be planted safely in spring if grown in one's own garden, and needing transference only from one position to another; but when the plants are obtained from a distance

it is safest to procure them in the fall, as they start to grow early in the spring, and one locality varies much from another, both in the time when plants are in active growth and the time when it is possible to plant them elsewhere. Both to those who have already a collection of Japan Irises, and to those who have none, the question of what sorts to plant is of great interest, for when they were introduced to the United States and Europe, varieties were, of course, named in each country, according to the fancy of the possessor, so that we can buy sets from different dealers and stand a good chance of getting duplicates though a different name be attached. In order to avoid this it is best to make a selection at flowering-time, as growers of hardy plants are usually glad to send cut flowers of different varieties for selection. In making a collection it is best to avoid the plants which produce flowers of large diameter, as the petals of such flowers lack substance. Preference should be given to plants producing flowers of good substance or the double-flowered varieties, the blossoms of which last are beautiful and durable when cut. When buying from a catalogue the mixed varieties must be avoided. It is better far to pay the price and get good ones to start with, and then by careful selection and seed-saving to raise seedlings at home, which will flower when two years old if the seed be sown in boxes when ripe, brought on in the greenhouse in spring, transplanted when large enough indoors, and later in the open ground. Plants thus treated will all flower, and the poorest of them will be better than low-priced kinds. Indeed, I have raised as good double varieties from seed as could be found among forty sorts imported from Japan.

As with many other plants, the more highly developed the flowers the less of seed we get, and the double varieties of Iris produce seed sparingly. The seed should be gathered when ripe and taken out of the capsule and cleaned, as there is a small worm that finds these seeds a comfortable place for winter quarters, feeding upon their substance as the days shorten.

The poor varieties weeded out from a lot of seedlings should not be thrown away, as they are admirably adapted for naturalizing in waste places where the soil is moist. In such positions the Japan Iris will hold its own against all other plants or weeds, and will flower year after year and reproduce itself from seed. Another point worthy of remark is, that when transplanting in the fall we should resist the temptation to cut off the foliage. The mature grass-like leaves are a great protection to the dormant buds below, and where appearances are not studied too closely the foliage should remain on the plants all winter, more especially if they have been moved, and the same remark applies to many other plants, such as *Eulalia*, *Arundo donax* and all Lilies.

South Lancaster, Mass.

E. O. Orpet.

Eschscholtzia Californica.

AMONG the most satisfactory annual plants, either for outdoor cultivation or for forcing, are *Eschscholtzia Californica* and its variety *crocea*. The plants are very easily grown and are most profuse bloomers, the bright orange or yellow flowers forming one of the most conspicuous spots in the garden. The seed may be sown out-of-doors in May, but plants started under glass early in April are more satisfactory, as they mature so much earlier and will often begin to bloom before the hot weather of August sets in. The blossoms appear most freely in cool weather, and in this locality are usually at their best when cut by frost in September. If the seed-pods are removed as soon as formed, the period of blooming may be prolonged almost indefinitely, provided the plants are protected. I have had plants to give a profusion of blossoms for more than two months. If the pods are not removed, however, the vitality of the plant is taxed to develop seed and the later blossoms are small and inferior.

Two or three plants which I had in the greenhouse last winter attracted much attention. In October, after frost had destroyed most of the plants, some young seedlings were removed to the house. They were shifted as needed, and finally, in four and a half-inch pots, were plunged in earth in a cool house, with a night temperature fifty degrees. From the first of March until June, when the house was cleared, the plants bloomed freely and continuously. Two of the plants, when at their best, had more than one hundred open blossoms at once, and the effect was most pleasing.

The chief objection to the *Eschscholtzia* for cutting is its habit of closing the petals at night. The blossoms last several days, however, and I have found them more satisfactory, and less inclined to close at night, the second or third day after cutting than the first. I have a vase filled with the flowers before me

as I write, and though they have been cut four days they are as bright now as when first cut. This plant should be more widely cultivated and more generally found in home gardens.

Orono, Maine.

W. M. Munson.

Correspondence.

Autumn Flowers at Passaic, New Jersey.

To the Editor of GARDEN AND FOREST:

Sir,—A good example of the Olcott system of making lawn was seen at Woolsons & Co.'s nursery a few days since. Pedigree grass-growing, as it is called, consists in sowing the purest available grass-seed in a sheltered place, as in a frame, where it is carefully cultivated and weeded from all rogues or foreign varieties. The true plats thus produced are cut up into small pieces, from one-quarter to one-half inch in diameter, and planted at some distance apart—in this case nine inches—in carefully prepared ground, to tiller out and fill out the lawn. The lawn here seen was a variety of *Agrostis*, planted about the middle of May, and now showing a nearly perfect mat of a uniform green. Apparently, the lawn only needed a rolling and the filling of a few vacancies, and was absolutely free from all but the one grass originally planted in small tufts. It will readily be believed that the initial weeding in the seed-bed is labor applied exactly in the right place, and the system seems as economical of labor as successful in producing a lawn of the species of grass desired.

Clematis paniculata, covering a wire trellis several hundred feet long, cannot be passed without note, though the plant has had its share of notice. It may be said, however, that among the numerous plants some were showing flowers larger than the type, but with all the elegance of the species. *C. Davidiana*, introduced a few years ago with some flourish, does not seem a plant likely to become popular, in spite of its "blue hyacinth-like flowers." Where space is not valuable it may have a certain value in the shrubbery, but its flowers are not very frequent or showy, and they are produced in the axils of the leaves and are practically stemless. The plant also has a certain interest as not being a climber as are most other members of the family. Other species in flower at the same time were *C. crispa*, *C. coccinea*, *C. flammula*, *C. stans*, *C. Viorna*, *C. tubulosa* and *C. Pierotti*.

Perennial Asters are interesting plants not nearly enough appreciated in our gardens. Unfortunately the names are very much mixed, and at present it is only by observing the plants in flower in nurseries that one can secure a collection without duplicates. The species here, such as *A. Novæ-Angliæ* and var. *rosea*, *Patmicoides*, *lævis*, *longifolius*, *bessarabicus*, *Herveyi*, etc., are said to have been identified by Asa Gray. The dwarf-growing Alpine Aster, which flowers in May, is one of the most satisfactory of the hardy Asters and should not be omitted from the choicest collection of hardy plants. Stokes' Aster (*Stokesia cyanosa*) was also in flower. This is an attractive composite with light purple flowers of beauty and distinctness, some three or four inches in diameter. A mass of *Plumbago Larpentæ*, with its neat foliage just beginning to take on bright tints, and covered with its rich blue flowers, reminds me that this is a plant which apparently revels in sunshine. In England, where it is much grown, there are frequent complaints of its doing badly and not flowering.

I noted many other beautiful flowers, *Anemone Japonica*, *Daphne Cneorum* (second bloom), *Veronicas*, *Tritomas*, *Sedums*, *Rudbeckias*, *Platycodons* and *Lobelias*, which add so much color to our gardens at this season, but whose glories will be eclipsed by the wonderful coloring which will soon surround us as ripening vegetation is suffused with autumnal tints.

J. N. Gerard.

Russian Fruits.

To the Editor of GARDEN AND FOREST:

Sir,—In your issue of August 3d, I notice in one of the always readable articles of your correspondent, Dr. Hoskins, a recommendation to the fruit-growers of New York to test the Russian fruits, especially the Apples, with a view to escape the troubles of apple-scab, etc.

This is commendable, because experiments are advisable in every business, especially if indulged in judiciously. The experience of others is an aid to individual judgment. The people of Iowa have tested the Russians zealously for about ten years; they have been urged and led along that path both by precept and example. In 1882 the new Russian fruits came, "a very great multitude," and in 1883-4 a series of disasters

nearly ruined the orchards of the state. Men were ripe for any trial that promised relief. Nurserymen eagerly stocked up with Russian fruit-trees of all sorts. Enterprising salesmen offered them at fancy prices, and everybody was ready to buy.

In an incredibly brief time the nurseries and orchards were testing the strangers. Now, in 1892, ten years from the start, a survey of the field is instructive. South of latitude forty-two degrees I know of no nursery offering Russian fruit-trees, except in a very limited way. Out of over three hundred varieties of Apples, I am propagating only two, and these more and more sparingly. Both are summer Apples, and, in my judgment, must disappear after a few more years, and their places be supplied with others. Cherries and Plums are in the same condition, the Pears nearly so. Whether at the end of another ten years anything but a memory of them will remain to southern Iowa is questionable.

Russian fruits are seldom seen in our markets. What have been offered have been of medium or poor quality. The trees in nursery and in orchard have suffered from various diseases, blight being most fatal. Nurserymen south of forty-two degrees have almost entirely ceased to grow them. North of that, the destruction and loss of credit have not been so great. In short, the whole matter rests upon that of locality, latitude and height above the sea. The centre of origin of the Russian fruits imported is in about fifty-five to sixty degrees of north latitude, and a change of ten or fifteen degrees of latitude is too much. Theory indicated this before the experiment, and experience has confirmed scientific prediction.

In the extreme north of New York Russian fruits may prove desirable. In the great fruit-belt south of forty-two degrees no experience justifies such a hope. The experience of Ellwanger & Barry at Rochester, of the Berckmans in New Jersey and of the very extensive and expensive trials in Iowa and adjoining states forbids it.

Des Moines, Ia.

C. L. Watrous.

Albino Orchids.

To the Editor of GARDEN AND FOREST:

Sir,—In your issue of August 17th one of your correspondents speaks of finding *Habenaria fimbriata* in its white form near Tannersville, New York. Perhaps it may interest her and others to know that I have found the same near North-east Harbor, Mount Desert, Maine.

Baltimore.

Mrs. Thomas Baxter Gresham.

California Roses.

To the Editor of GARDEN AND FOREST:

Sir,—There are few places, and perhaps none, in the Union where so many men of affairs devote their leisure to the cultivation of Roses as Oakland. The evidence of this can be seen any day in the abundance of cut roses which are carried across to the city. Many of these amateur cultivators are enthusiasts, and their conversation is apt to centre on the merits of some new or old Rose, for their collections include hundreds of distinct varieties.

That the Rose is well at home in California goes without saying. As a climber it goes skyward like a Wild Grape; as a standard it grows into trees eight and ten feet in height, with a stem fit for a handspike, and as a shrub it rivals in luxuriance the Willows by the brook-side. It requires, as a consequence, plenty of room here. If the directions given in books for other climates were followed, our Roses would be packed together like bristles in a brush.

Some Roses that have a good reputation in the east or abroad are of no value here, while some of our best kinds have little reputation elsewhere. Of the first class we may mention, among the Tea Roses, Marie Guillot, Madam Bravy and Etoile de Lyon; among the Hybrid Perpetuals, General Washington, Madam Charles Wood and Dinsmore, and among the Bourbons, Queen of Bedders and Appoline. Of the other class the following are a few examples: The Tea Rose Laurette, catalogued by only a few growers in the east, grows into a tree eight feet high, with a stem two and a half inches in diameter, in five years from the cutting, and its flowers are exceedingly bountiful, beautiful and constant. Reve d'Or, Noisette, is more valuable than Maréchal Niel. It is a wonderful grower, always in bloom, and the flowers lack but little of being as fine as those of Maréchal Niel. The little Polyantha Rose, Cecile Brunner, so lightly esteemed at the east that half the growers do not list it, within a few feet from where I am writing forms a hedge four feet high, and this would be much higher were it not cut back twice a year.

There is scarcely a month in the season when it is not a mass of bloom. The buds have few rivals for boutonnières, and the full-blown flowers, at least two inches across, are beautiful almost beyond comparison for decorative purposes. Our Italian florist says, "Everybody like-a de baby roses." Perle d'Or is a fit companion for Cecile Brunner, and the two are worth more here than all the rest of the Polyantha class.

Of course, the behavior of Roses is not uniform in California, for the state has such a wide range of altitude, latitude and longitude that it affords almost every variety of climate, from perpetual summer to eternal winter.

Oakland, Cal.

H. G. Pratt.

Cypripedium Edwardii.

To the Editor of GARDEN AND FOREST:

Sir,—A seedling *Cypripedium* of much interest has just flowered in the collection of Mr. H. Graves, Orange, New Jersey, which has been named *Cypripedium Edwardii*, in honor of the son of Mr. Graves. It is a cross between *C. superbians* and *C. Fairieanum*, and was raised by Messrs. Pitcher & Manda at the United States Nurseries.

The plant is very compact; leaves, about five inches long and one and one-half broad, rounded at the ends, deep green, faintly tessellated and glossy; scape, green, pubescent, erect, monoflorous; flower, large; dorsal sepal, two inches long, white, tinted with green at the base and vinous purple near margin, rayed and reticulated with green, many of the rays speckled with brown; petals, two and one-half inches long, undulated and drooping as in *C. Fairieanum*, margined with black hairs; the border is vinous purple speckled with black; centre, translucent, with parallel veins running from base to apex; basal third, thickly dotted with black; pouch, two inches long, narrow, pale green, with brighter reticulations dotted at base and on inside with vinous purple, shaded with brown on front; staminode, large, netted with bright green.

Orange, N. J.

Recent Publications.

Annals of Horticulture in North America for the year 1891. By L. H. Bailey. New York, The Rural Publishing Company.

All persons who take more than a superficial interest in horticulture will be grateful to Professor Bailey for this record of the labors of a year in his special field, and still more grateful for the assurance it gives that these volumes can hereafter be expected regularly. As the series grows it will be invaluable for reference, a treasury of horticultural knowledge, and a history, let us hope, of steadily growing interest and continued progress. Each of the volumes is much more than a mere witness of current events. The first one, for example, contains a list of kitchen-garden vegetables, and the most important piece of work in the present volume is the elaborate census of our native plants which are, or have been, cultivated.

An examination of the list, which covers sixty pages, will surprise most readers, for the extent to which our fields and woods have enriched the gardens of the world is not generally realized. Professor Bailey estimates that north of Mexico our continent contains 10,150 known species of plants, distributed in 1,555 genera and 168 families. This census makes record of 2,416 species, representing 769 genera and 133 families. Of these species 1,929 are now offered for sale in America; 1,500 have been introduced into England, 487 of which are not in cultivation in America. Nor does it follow that the species introduced into England are all now cultivated there; the record simply shows that they were once introduced there and when this occurred. Many of the southern species were procured by English collectors from the West Indies or from Mexico. Some of these may never have been seen outside of botanical gardens, and a few may have been lost to cultivation.

It is not strange, as Professor Bailey points out, that American plants should have been first cultivated in Europe, where the growing of plants for ornament had been developed into an art while the civilization of this country was yet in its pioneer stage, and, of course, unfavorable to gardening of this character. Besides, it seems to be the rule that horticulturists are attracted by the unfamiliar and strange appearance of exotics, and that novelty is quite as strong an influence as intrinsic merit in favoring the dissemination of plants. Drummond, Fraser, Douglas, and their contemporaries, as well as our own early botanists, with John Bartram at their head, were all assiduous in sending seeds and living plants to the gardens, and especially the botanic gardens, of Europe. It is worth noting that many of these early introductions have been so modified by long domestication that their appearance seems strange to

one who has only known them wild in their native home, and Mr. Dyer, the Director of Kew Gardens, asserts that even in the collection there the feral types are often wanting, and only cultivated forms are represented.

The list of fruits, vegetables and ornamental plants introduced into American trade during the year 1891 includes 884 species and varieties as against 575 for the year before, and 434 for the year 1889. This increase is due partly to the fact that increased experience and facilities enable the authors to make a more complete record. But the introduction of new Roses, Chrysanthemums, Carnations, Cannas and Geraniums, as well as of native plants, was unusually large last year, and shows a broadening and more active trade. Of the 884 introductions 668 are ornamental plants, 108 are fruit-plants and 108 vegetables. Of 188 native plants introduced twenty-four are fruit-plants, and twelve of the ornamental plants have edible fruits. Analyses like these are interesting, as they indicate in a striking way the tendencies, the varying vigor and the shifting fashions of our horticulture.

Other important titles in the Special Annals are the Plant Portraits of the Year, A Directory of the important Horticultural Societies in North America, A Directory of the persons in charge of horticultural work in the Experiment Stations, The Botanic Gardens of the World, Title-index to the horticultural literature of the Experiment Stations during the year, A Subject-index to the same, Horticultural Books of 1891, Tools and Conveniences of the year.

The first part of the volume, or the so-called General Annals, is a compendium of information on a great variety of subjects, which have been carefully selected and skillfully arranged. As an example of the quality of this portion of the *Annals* we quote the following passages on spraying machinery and fungicides:

"In spraying machinery there has been great activity in the manufacture of various styles of knapsack-pumps, and several horse-machines have been put upon the market or have received marked improvements. The most important departure of the year, however, is the labor of the committee appointed by the Association of Agricultural Colleges and Experiment Stations, to consider means by which uniform sizes of fittings can be secured for all spraying-machines. This committee, appointed in November, 1890, consist of W. B. Alwood, of Virginia; D. G. Fairchild, of Washington, D. C., and James Troop, of Indiana. It has secured the agreement of nearly all manufacturers to use standard sizes of threads and other fittings, and the advantages of its labors will be placed before the public for the season of 1892.

"In the treatment of plant diseases, two copper-sprays continue to gain favor, and their use for control of diseases of the Grape has already come to be an established practice among growers. It is a question of but two or three years before the leaf-blight of Quinces and Pears, Apple and Pear scab, and the old Potato-rot will come under the control of the general grower. There is a distinct movement in favor of the ammoniacal carbonate of copper as compared with the Bordeaux mixture, as it is cleaner, cheaper and much more easily used. Among new fungicides there are two which demand record here. The more important is that prepared by the Division of Vegetable Pathology of the National Department of Agriculture last year as 'Mixture No. 5.' It consists of equal parts of ammoniated sulphate of copper and carbonate of ammonia, thoroughly mixed, and put up in air-tight cans. A pound of this dry mixture is used to thirty to fifty gallons of water. The material is cheap, costing about forty-five cents per pound, is easily prepared, and can be kept in the dry state until desired for use. This material, which is essentially a dry eau celeste, has been used with good results upon those fungi for which the ammoniacal carbonate of copper and Bordeaux mixture are employed. Lodeman has found that the chloride of copper possesses merits which entitle it to trial for the common plant diseases. When used at the rate of three ounces in twenty-two gallons of water it gave better results upon Squash-mildew (*Oidium erysiphoides*, var. *Cucurbitarum*) than did the Bordeaux mixture."

The last serial issue of *Economic Fungi*, by A. B. Seymour & F. S. Earle, is a double one, including Fascicles iii. and iv., numbers 101-200. In it the authors have confined themselves to "fungous parasites on forest-trees and other woody plants indigenous or cultivated for ornament."

Not less than sixty-eight ligneous plants are enumerated in the list of host plants. Many of these have but a single fungous enemy given, while others bear four representatives, as, for example, the Honey Locust. Five species of Maples are represented, and among these the most conspicuous fungus

is the *Rhytisma* of the White Maple, which produces large irregular shining jet-black patches upon the leaves, familiar to many students of forest-trees. It is found upon the Red Maple also, where it disfigures and damages the foliage. Two anthracoses are shown, *Glœosporium decolorans* on Red Maple and *G. saccharinum* upon the Sugar Maple. This latter does great damage to the leaves, causing them to turn brown prematurely in large patches. There is a showy mildew of the Maple which forms a cobwebby covering to the leaves, and sometimes is particularly destructive to seedlings in the early autumn. A similar mildew of the same genus (*Uncinula*) is shown upon the Horse-chestnut, but the more common and vastly more destructive enemy to this handsome shade-tree is *Phyllosticta sphæropsoides*, which causes the foliage to turn of a reddish brown color early in the season. In August many trees are sadly blighted by this fungus and almost look as if they had been scorched by a fire.

Nine fungi are shown upon eight members of the Rose family. There is a conspicuous parasite upon the Shad-bush that covers the leaves with a dark, almost black coating. When a bush is affected in one part it usually is infested elsewhere, thus giving the plant a peculiar appearance. In *Podospheera Oxyacanthæ* we have a good illustration of a mildew that infests a large number of hosts in the same family, such as the Hawthorn, Choke-cherry, Meadow-sweet and Hardhack. When this appears upon a cultivated plant it may be remembered that it breeds abundantly upon wild plants just outside the garden fence. This is likewise true of the Peach curl (*Taphrina deformans*), which is shown upon leaves of the Chickasaw Plum and the wild Black Cherry. This last also harbors the serious leaf-blight of the cultivated Cherry that has defoliated the orchards in the west of late years.

The Elm family shows eleven fungi, and the Elms proper five. There is a mildew similar to the one upon the Maple, and identical with the one met with upon the various species of Ash and the Beech. It is interesting to note that forest-trees of widely separated orders become the adopted home of the same parasite. Usually a fungus does not go outside of one family, but in this case we have a striking exception. In the Walnut family there is one fungus that is given upon four hosts. This *Microstroma Juglandis* is one of the most showy of moulds, coating the affected parts of the foliage with a white layer. It is common to both *Hicoria* and *Juglans*, and is one of the many instances where the presence of a fungus indicates close relationship.

The largest number of fungi in the century is in the Oak family, no less than twenty-four being enumerated, and half of these are upon members of genus *Quercus*. Mildews are the prevailing form of parasites. There are no rusts represented nor smuts, while there is a goodly number of blights and a few anthracoses. One of the most showy and injurious species is *Marsonia ochroleuca* upon the Chestnut. Others are two leaf spots of the Hazel, and the Anthracnose (*Glœosporium Canadense*) of the White Oak. This latter has been the subject of frequent remark in all parts of the country, as it causes the premature dying of the Oak-leaves to a conspicuous degree.

Among the Poplars and Willows there are a number of injurious pests, one of which is a genuine rust—namely, *Melamporsora populina*. The most conspicuous fungus here is the black *Rhytisma* of the various species of Willows. One of the handsomest as well as most common of the mildews is upon the Willows.

Notes.

The horticultural and floricultural work in the French section of the Chicago Exhibition will be placed in charge of Monsieur Le Fevre, head-gardener of the city of Paris, who arranged and superintended the beautiful Trocadéro Gardens at the Paris Exposition of 1889.

Mr. James MacPherson writes to the *Country Gentleman*, that in the yard of the New Jersey State Insane Asylum at Trenton there is a specimen of English Yew (*Taxus baccata*) which originally came from Stoke Pogis church-yard, England, and it is now eighteen feet high, of a perfect shape, and has a spread of thirty feet.

Speaking of the timber of the Gum-tree, which in England is absurdly called Satin-wood, a Minneapolis writer says that in price it is about the same as that of Yellow Pine, and as a finishing lumber it has all the good qualities of that, with few of its imperfections. It will not sliver when used as flooring and as interior finish is susceptible of high polish.

A correspondent writes that the practice of removing tassels from Indian Corn, to which we alluded on page 384, is practiced largely in southern Europe, where only a few of the male flowers are left to fertilize the ear. The tops are used as green fodder for cattle, which is very scarce during the summer months.

Some months ago we published an appeal for the preservation of Poe's cottage, which stands in a much-neglected condition at Fordham. Now we learn that it is to be preserved, although not on its present site. It has been bought by a well-known Catholic publisher, and will be removed to his grounds, which, however, are in the near vicinity, and transformed into a library and studio for his use.

The recent blueberry season in Maine was a very good one, and surprising accounts have been given of the activity of the canning factories where this fruit is preserved. It was not uncommon, we are told, for 700 or 800 bushels of blueberries to be delivered at the door of a single factory during one morning, and as all had to be canned within the twenty-four hours, operatives were kept at work until one or two o'clock at night. Whole schooner-loads of the canned product were shipped to Boston and other seaports.

At a recent convention of the American Florists in Washington the question, What are the twelve best monthly or ever-blooming Roses for amateurs? was answered by Mr. P. O'Mara, of New York, and Mr. E. G. Hill, of Richmond, Indiana. Both lists contained the following Roses: Agrippina, Clothilde Soupert, Souvenir de Malmaison and Madame Hoste. To these Mr. Hill added Mrs. George Paul, Crown Princess Victoria, La France, Duchess of Albany, General D. Mertchansky, Sombreuil, Meteor and Grace Darling; while Mr. O'Mara named Hermosa, Perle des Jardins, The Bride, Sunset, Catharine Mermet, Mrs. DeGraw, Bon Silene and Madame Pierre Guillot.

A late number of the *Gardeners' Chronicle* gives the figure of a curious hybrid between a Black Currant and a Gooseberry, in which the hanging fruits resemble a currant, while the leaves resemble somewhat those of the Gooseberry. The fruit appears in bunches of from two to four. They are about the size of black currants, but in color like a red gooseberry, and are covered with fine hairs and destitute of seeds. The flavor partakes of that of a gooseberry and a black currant, and seems to Dr. Masters to be an improvement on both. If gooseberries of improved flavor can be grown in clusters and on a bush without spines, Mr. Culverwell, the producer of this new hybrid, will prove a benefactor to horticulture.

A correspondent of the *Journal of Horticulture* names the following as the best of thirty-six varieties of Sweet Peas raised by Mr. Henry Eckford, and displayed at a recent exhibition in Shrewsbury: Emily Eckford; this approaches a true blue, the wings of a well-marked cerulean tint, but the standard suffused with reddish mauve. Peach-blossom; the wings soft rose, shaded with cerise, the standard rosy red at the base, shading upward to pale pink. Ovid; one of the most richly colored varieties yet raised—a brilliant rosy carmine. Royal Robin; a clear pink, with blush wings and a white keel. Venus; a blush-colored flower, with a suffusion of pale yellow, very distinct. Stanley; a dark flower, with standard and wings brownish purple, almost black. Blushing Beauty; soft pink, suffused with lilac. Lady Penzance; large smooth flowers with a prevailing color of lustrous rose.

The following brief paper was read by Mr. T. T. Swinburne at the last session of the American Association for the Advancement of Science: "It is suggested that the American Association for the Advancement of Science, in the absence of a national flower, request the management of the Columbian Exposition to adopt the Columbine as the flower of the Fair, leaving the national flower, whatever it prove to be, to grow in popularity. Its name comes from the same root as Columbia, a name our country often bears; it is classed with the Aquilegia or eagle variety, because its petals end in spurs resembling the talons of an eagle; it grows in red, white and blue, our national colors; it has five trumpet-shaped petals, corresponding to the five points of the star upon our flag, and these are grouped around a central shaft, similar to the arrangement of the states around the central government; and it is indigenous to the North American continent, a hardy perennial and wild flower that is found in every part of our land, growing even upon the Rocky Mountains, and in the very heart of the country. It is appropriate in name, form and color. Its name suggests Columbia, and its form is the proto-

type of the Phrygian liberty cap, the head-dress of Columbia, and an exact copy of the cornucopia, the symbol of the Columbian Exposition."

"It is worth one's while" says a recent writer in a Boston journal, "to go to the Parker Memorial Building to see the labor of love which is being done by the young ladies who are interested in the Flower Mission. Inside there are groups of girls sorting the flowers, and around the door stand groups of children, some with baskets, some without, all lingering to obtain their much-prized posies. When the flowers have all been arranged, the work of distribution begins, and the young ladies start about on their errands which are to make so many people happy. At the hospitals, patients, nurses and surgeons are waiting for their visits, and the thankful looks and the grateful words repay them for all their trouble. To the crowded workshops some of the girls go and pass around among the workers, giving to each a bouquet. These are cherished, and when the day's work is done they are taken home to brighten up the ordinarily cheerless rooms in dark tenements. On a single day in July, and not an exceptional day either, 1,594 bunches of flowers were sent out to various institutions, besides some which were given away at the door of the Mission; and, in addition, fruits, jellies and vegetables were largely distributed. Nevertheless, the demand was always greater than the supply, and there is need for all livers in the country or owners of urban or suburban gardens to be constantly reminded of the existence of these missions, and of the infinite pleasure they give to the very poor."

The "Sacred Lotus," *Nelumbium speciosum*, has found a congenial home in one of the small lakes of Central Park, New York City. It has been established three years, and this season covers an expanse of considerably over half an acre, being, probably, the best example of the plant to be seen in the United States. The plants are thrifty, with leaves of the largest size, and at present hundreds of the noble flowers are open, while innumerable seed-pods show the wealth of bloom of the earlier season. Given a soil in which the tubers may mature properly each season, this *Nelumbium* will not only grow luxuriantly, but it can be counted on as perfectly hardy. In the large fountain-basin at the head of the Mall there are some exceptionally good specimens of *Nymphæa Zanzibarenensis*, both the blue and red varieties. The tubers are said to be three years old. The large highly-colored flowers and ample foliage attract more attention than any of the other varieties in the same basin. *N. Devoniensis*, *N. Sturtevantii* and *N. dentata* are represented, but these night-flowering varieties are not seen to the same advantage here as in such basins as Union Square, where there are electric lights. Masses of the Egyptian Papyrus with the *Nymphæas* make an effective picture in the upper basin, it not being at all crowded, and there being ample margins of water among the various plants. Abundant spaces of clear water around aquatic plants are the main essential to the perfect harmony and beauty of a water-garden. A tank or a lake covered entirely, even with the choicest plants, is, at its best, commonplace.

At the late Begonia Conference at Chiswick, England, the remarkable evolution of the present race of garden Begonias was illustrated by a collection from Kew, which showed the various stages of its progress from the original forms. In the *Gardeners' Chronicle* the singular fact is stated that several of the original species which formed the starting-points of this remarkable development have apparently disappeared from gardens, the parents having been completely superseded by their more attractive progeny. Historically, this is unfortunate, but the loss is not so great as it seems, for it must be remembered that these plants, unlike Orchids, have not been exterminated in their native haunts, and they can be reintroduced. Again, a much more complete record, both in the way of illustration and verbal description, has been made than was formerly done. It is not long ago since the source of novelties and the origin of crosses were often carefully concealed, and sometimes deliberately misrepresented, in the supposed interest of trade. We agree with Dr. Masters that it would be well if the hybridizers of these plants should in the future make an attempt to secure greater hardiness and greater variety, to form new and distinct races, and that they should give over attempts to produce flowers which are merely larger than they are now. If hybridizers and cross-breeders will follow the natural lines of the flower, will enhance and emphasize them rather than attempt to reduce them all to one uniform circular outline, they will not create flowers which, so far as their form is concerned, might be Hollyhocks or Double Balsams or Camellias or anything else than Begonias.

Legislations against Injurious Insects and Plant Diseases.

THE amount of money which is lost every year in this country by the ravages of insects and of fungus plagues is so enormous that any attempt to state the figures in hundreds of millions of dollars would sound like an exaggeration. We are constantly reminded, however, of these losses, and within a week past two of the bulletins received from state experiment stations contain statements which will help us in forming some estimate of their extent. The September bulletin from Michigan asserts that the loss in that state this year to the Oat crop alone by the single disease known as smut exceeds \$1,000,000. Professor J. B. Smith, the Entomologist of the New Jersey Experiment Station, in the report for the year, just received, asserts that insects exact a tax of fully ten per cent. on the farm products of that state, and this tax is all taken directly from profits. Dr. Shimer, whose estimate has been approved by the highest authorities, has stated that in one year the corn and grain crop of the single state of Illinois suffered to the extent of \$73,000,000 from the chinch-bug, and Professor Comstock estimated that the ravages of the cotton-worm in years when it was generally prevalent caused the loss of \$30,000,000. If the agricultural products of the United States approach \$4,000,000,000 annually, and one-tenth of this is destroyed by insects, the addition of the loss caused by fungus diseases would easily swell the figures to a total destruction of five hundred millions per annum. Whether half a billion dollars, or, say, a million and a half of money every day, is over the truth or under it as an estimate of this loss, the fact remains that the amount of the destruction is quite beyond the grasp of the ordinary imagination.

The increased knowledge of the history and habits of destructive insects and of fungi which cause plant diseases is the most striking feature in the progress which has been

made in agriculture and horticulture during the last twenty years. We can all remember when these losses were endured as a matter of course, and with scarcely an effort to avert them, while now there is an organized corps of skilled investigators in every state who are studying and experimenting to discover the best practical means of defeating these enemies, and some knowledge of the latest and most approved fungicides and insecticides, and some familiarity with the best machinery for applying them, is a necessary equipment for the ordinary farmer and gardener. But these enemies come in such countless multitudes, and their operations spread over so large a territory, that no effective stand against them can be made without concert of action. It is useless for one man to rid his Plum-trees of the black knot or his Apple-orchards of the tent-caterpillar if his neighbor allows both the insect and the fungus to breed on trees in an adjacent lot. It seems reasonable, therefore, that some legal means should be devised of compelling land-holders to keep their premises free from certain kinds of insect and fungus pests.

The state of Michigan was visited with some severe criticism a few years ago for enacting a law to suppress the peach yellows, and an attempt was made to overthrow a similar law in New York state by persons who contended that the yellows was not a specific disease which was communicable. Time, however, has vindicated the wisdom of this law, and now not only has Michigan a new and more effective law, but Delaware, New York and California have passed enactments which look in the same direction. In New Jersey the experiment station authorities have the power to destroy crops which are infested with new and dangerous fungi—a law which was passed as a result of the investigation of the cranberry-gall fungus two years ago. In California and Washington there is an inspector of fruit pests, who has power to quarantine fruit packages, trees, plants, cuttings and cions which are believed to be infested with insects or disease germs liable to spread contagion, and this quarantine is good not only against foreign countries, but against the other states of the Union. This is the first organized effort to exclude contagious plant diseases from a given territory, and if it is honestly executed it will be watched with great interest. It is worth noting here that many nurserymen in the east argue that the prime purpose of this law is to prevent competition in the nursery business. Beyond these laws there have been sporadic efforts to exterminate some particular pest, like the attack in Massachusetts upon the Gypsy-moth, or the efforts of the General Government to afford some protection against the grasshoppers in the west. But, after all, it is plain that, as compared with the magnitude of the evils, the efforts made by state governments for the protection of the property of their citizens have been slight and desultory.

In a few of the states, laws to prevent the spread of noxious weeds are in force, and, of course, laws against insects are based on the same principle. And why should not the protection of plant life be as justifiable a subject for legislation as the protection of animal life? The state will spend hundreds of thousands of dollars to stamp out pleuro-pneumonia from its herds, and yet the pecuniary loss and the discomfort to society from this disease are no greater than what happens from the destruction of the vineyards by the phylloxera or black rot. To be effective, however, legislation must be based on the best available information, and it should be general. It is not to be assumed that the members of our state legislatures are sufficiently well acquainted with the habits of insects or the life-history of fungi to devise the best means of attacking them. But there are in almost every state persons who are skilled in economic entomology and in mycology, and their knowledge and experience are available. There is an association of economic entomologists who represent every part of the United States. There is an association of officers of the experiment stations and the agricultural colleges, whose business it is to look after the interests of agriculture and of horticulture. This certainly is a subject to be

taken up by some body of national importance so that a code of laws, which are general in their character and which would be applicable to the needs of all the states, could be devised. Bills should be drawn which would be comprehensive enough to include the most dangerous contagious diseases of plants and the most destructive of insects, and they should be framed to fit the special needs of different states. There is little doubt that such bills could be pushed through to enactment if the association of station officers and, through their influence, the various state boards of agriculture would urge their importance upon our law-makers. Only by some strong movement of this sort can we hope for a code of laws under which a hopeful contest can be waged against the enemies of our crops. The enforcement of this legislation might cost considerable to begin with, but the expense incurred would be small compared with the enormous drain upon our resources from the unchecked, or only partially restrained, ravages of these pests.

An American gentleman, writing from England, notes two things in particular which help the people there to get more for their money in the way of recreation than we do here. One of these is the enormous amount of common land so easily accessible from the great cities, and the other the fine roads for bicycling, a form of recreation in universal vogue. In his native city, Cincinnati, this gentleman remembers that it was almost impossible for the boys to have a game of base-ball, and the few places then available are now covered with buildings. He says: "None of Cincinnati public parks are ever used for games, and I don't think many of our western cities allow such use of their parks. Here nearly all the parks have immense spaces reserved for cricket, tennis and the like, and the London vestries are continually acquiring new land for recreation purposes."

While Cincinnati is exceptionally backward among large western cities in providing proper park facilities, the charge of not permitting a sufficient use of the parks for games would certainly not hold against Chicago, where the people enjoy the parks to a remarkable extent. Here in New York and Brooklyn, as well as in Boston and other Atlantic cities, ample facilities for popular recreation are provided in the parks. In Boston the open-air gymnasiums for men and women on the Charles-bank are such gratifying successes that a number of others are to be established in various sections of the city. The Earl of Meath reported to the London park authorities most enthusiastically on these institutions, and, in consequence, the example of Boston has been followed by the establishment of fourteen gymnasiums on a similar plan in the British metropolis.

Although England is very fortunately possessed of ample open-air spaces near her great centres of population and makes appreciative use of them, neither in beauty of landscape design, tastefulness of maintenance, or adaptability to their purpose do the English public parks, as a rule, approach the great parks of our own cities. But there is great room for the growth of an intelligent sentiment in favor of public parks in this country. Many of our great cities are alive to the advantages of spacious park-areas; but even here, the oldest, the most famous and the most useful, because the most beautiful, parks are in constant danger of confiscation or perversion to some special purpose, which would destroy their highest value as recreation-grounds for the entire population. On the other hand, the rapidly growing cities of moderate size, which in a decade or two more will rank as large centres, have not been alert to make provision for the future by taking for park purposes attractive suburban sites. Such sites may now be obtained for a trifle in comparison with what they will cost when the absolute necessity actually arises. And then it will too often happen, when the need does become urgent, that the favorable sites are built over or in some way ruined for park purposes.

Overland in the Cayuga Country.—III.

FROM Farmer Village an old "angling" road runs over the country to Ovid, a quiet village midway between the two lakes, Cayuga and Seneca, and which commands a view of both. This was in early times a famous Wheat country, and much of the staple is still grown, with as great yields as ever. But the old line of farming is not paying well, and the younger men are branching out into specialties. In Ovid is perhaps the most typical example which I have found of the success resulting from persistent and thoughtful effort in a minor branch of agriculture, all the more remarkable from the fact that the man has labored without instruction in a comparatively isolated inland town. This man is a berry-grower. Seven years ago Mr. Banker had one and a half acres of land, a very poor house and few of the conveniences of living, and was \$200 in debt. He now owns sixteen and a half acres, is laying up money, has built a new house and furnished it well throughout, and his children are going away to school. This he has made legitimately from the land, with no capital and no help. The neighboring farmers offer to sell him land, but he wisely concludes that sixteen and a half acres is enough, and will not buy more. I have never met a happier and more contented farmer. "I have just enough land to keep me busy, and not enough to work me to death," he remarked, "and I make a good living and have all the fun I want. No other business has any temptation for me." The largest part of Mr. Banker's business, probably, is in raspberries. These he sells both fresh and dried. He has a home-made evaporator, in which he manufactures about a ton of dried product annually. Among black raspberries he finds Gregg best for selling upon the daily market, and Ohio best for drying. Among the red Raspberries he still grows the Red Antwerp; with Early Richmond for the first markets. Mr. Banker makes a strong point of close-planting of the Raspberry, and rightly, too, I think. His rows for all varieties are seven feet apart, but the plants stand only two feet apart in the row. This thick setting brings earlier berries and gives more bearing surface per acre, and as he thins the growing canes severely and gives excellent cultivation, the plan succeeds admirably. But his strongest point in favor of this close planting is the smothering of grass and weeds, and the consequent great saving in hand-labor. He seldom hoes his plantations after the first year, and they remain clean. He declares that if he had learned this simple thing early in his experience, he would have been much better off to-day. It is needless to add that Mr. Banker believes in thorough work. In 1890 he bought five acres of waste bush-land near the village at a cost of \$300. This was tile-drained and thoroughly improved, and was set to black Raspberries in the spring of 1891. The improvements and plants cost \$200. This year he sold plants to the amount of \$175, and he estimated that the crop upon the vines would easily clear off the remainder of the \$500. Judging from the remarkable crop the bushes were carrying, I am convinced that he is right.

It is not far from Ovid to Romulus, and at this hamlet we came upon the Niagara Grape at its best. It is impossible to estimate the number of acres planted in this Grape from East Varick on Cayuga Lake to Kendaia near Seneca Lake. Mr. O. F. Reed, at Romulus, has the management of 590 acres of Niagara vineyards. This immense area is divided into three portions, each owned by a different company, but belonging to practically the same parties. The King Niagara Vineyard Company owns 150 acres, the Cayuga Lake Vineyard Company, 205 acres, and the Seneca Lake Vineyard Company, 235 acres, and these represent three solid blocks of the areas mentioned. These vineyards are all young, the oldest having been set but four or five years. The labor problem, therefore, has not yet presented itself in its full force, although Mr. Reed is now considering plans for securing sufficient pickers when needed. A crop of 70 tons is expected from one vineyard this year, and 140 tons from another. When the vineyards are eight years old the crop is expected to be from 2,500 to 3,000 tons annually. "No, we shall not try to sell it all as green fruit," he replied, in answer to a question. "We may make some wine, but we are looking more especially to unfermented grape-juice as an outlet for our crops." He then explained the process of making this article, as follows: Grind the grapes coarsely, taking care not to crush the seeds. This should be done in the afternoon. Place the material in tubs. The next morning, filter through paper, and heat nearly to the boiling-point and remove scum. Filter again, heat to nearly boiling-point and bottle. All those great vineyards, like that of Moore's Diamond, at Farmer Village, are trained upon the Kniffen system, and the tying is done almost entirely by

women. For this training two wires are used, and in these vineyards the lower wire is three feet from the ground and the upper one five and a half feet.

About fifteen miles from Geneva the horticultural region was left behind, and we came at once into general farming on the high land well up between the lakes. The whole country is admirably adapted to fruit of various kinds, and the time cannot be far away when the farmers will believe that fruit-growing is more profitable in this region than hay and grain. The country becomes much lower northward, and rolls away on all sides in mighty billows, until lost in the blue hills beyond the lakes. Near Geneva, beyond the foot of Seneca Lake, is the farm where John Johnston did the first tile-draining done in America. The old house still stands as he left it, with low ceilings, quaint "cubby-holes" and curious old latches. The farm is now owned and managed by Mr. Charles R. Melten, a young man of spirit and intelligence, who makes the most of his opportunities. "The old farm still outdoes any of its neighbors in productiveness," he remarked, "and I attribute the fact to the good old tile-drains and to the careful management which the land received in its early days. That field over yonder we always expect shall give us forty bushels of wheat to the acre, and last year it gave us an average of forty-two bushels and a peck." Adjoining the old Johnston farm is Rose Hill, the finest farm homestead between New York and Chicago; this is the estimate of a committee of appraisers to award damages entailed by a new railroad which cuts off one corner of it. Originally it contained over 1,100 acres; it was settled early in the century by a Virginian by the name of Rose. The present house and appurtenances are palatial, and of a type very rarely seen in American country-seats.

Cornell University.

L. H. Bailey.

The Old Southern Country-seat.

THE house in which a man lives goes far toward disclosing not only his tastes and intellectual development, but also his habits and modes of living. It has always seemed to me that the old southern homestead of the better class was peculiarly characteristic of our people in the halcyon days before the war. A thousand things told of boundless and tireless hospitality. The sagging "big gate" on the public road, one of whose posts, at least, was often a living tree, while extremely hard to shut, would open almost of its own accord. Besides, it had a great habit of hanging wide open as if inviting every passer-by to enter and make himself at home. And the chances were that the yard gate had the same habit. Inside, the shaded walk was broad and ample, as if many visitors were expected to walk abreast between the files of stately Box-trees up to the mansion, whose porch and hall and rooms and all their belongings were of the same generous dimensions. The kitchen fireplace was huge enough to cook for an army. An abundance of roomy arm-chairs, made of native wood and bottomed with native bark, offered comfortable nesting-places, so comfortable that it seems as if chair-making is now one of the lost arts.

The architecture of the building depended, of course, on the era of its erection. If early in the century, sharp roofs and dormer-windows were apt to prevail. Later, just previous to the war, hip-roofs abounded. Whatever the style, the rooms were almost sure to be large and square, and there were plenty of them. Eighteen feet square was a favorite size, though many were larger and few smaller. The house was invariably white, with green blinds; with their accessories of green trees and dense shade, these colors were beautiful and appropriate beyond all others. Red kitchens, smoke-houses, carriage-houses and other outbuildings lent picturesque to the scene. The palings, generally of large ornamented posts and small pickets, were also invariably white. Hedges in the way of enclosures were practically unknown, while ornamental hedges of Box were common. Cedar was also used for this purpose, though to a much less extent on account of the great care necessary to keep it trim. Flowers were nearly all grown in the vegetable-gardens some distance to the rear of the house, but there were always some Roses along the front walk, and often a bush of running Roses trained on one side of the porch. But little attention was paid to pot-plants, the Geranium taking precedence among the few flowers grown. In most yards no sowing of grass-seed was necessary, the native grasses, if protected from weeds, giving usually an excellent sward. Protected by the fallen tree-leaves purposely left in autumn, it remained green from the uncovering in early March till the trees again cast down its winter robe of russet-brown. Few Oak-trees were located in the yard, or at least to the front of the house, on account of

their injury to the grass, while under most of the other trees planted for shade or ornament it grew even more luxuriantly than in the open.

Riding was almost universally practiced by both sexes, and the horse-block from which the ladies of the family reached their saddles was a fixture in every homestead. Sometimes this "block" was a granite cube rudely dressed by the farm mason, or may be a lichened boulder which nature had placed just in the right spot or very near it. Almost every place had its pigeon-cote; some of these were elaborate and ornamental, housing many hundred birds. The squabs were occasionally killed, but generally the pigeons were allowed to multiply undisturbed, much to the annoyance of the overseer, who was constantly complaining of their attacks on newly planted corn and peas. Few places had wells, or, having them, used their waters. Everybody preferred spring-water, which was considered better and more wholesome. Among the hill-districts these springs were often wonderfully bold and beautiful, their sparkling waters pausing a moment in the natural basin of solid rock, and then dashing off between mossy roots and lichened stones down a glen all greenness and shade. That these springs were all the way from a hundred yards to half a mile from the house made little difference as things then were. There was always a swarm of nimble-footed pickaninnies ready for this or any other errand. Indeed, some such light service was necessary to keep them out of mischief, and to drive cows, mind gaps, blow fires akindle, and keep chickens out of the garden left enough idlers to give a world of trouble about the kitchen and back-yard. "I use daily a five-hundred-dollar candle-stand, a four-hundred-dollar washstand, and a towel-rack nearly as valuable," was the mild and oft-repeated joke of an old gentleman who was served by a swarm of these sable urchins.

But all these things belong to a past whose remoteness cannot be measured by years, because they are a part of a different era, a different order. The chances are that the old homestead has long since gone to decay. All but a pitiful corner of the spacious garden has been turned into a corn-field; browsing stock have played havoc with the grass and shrubbery of the yard; the shorter-lived shade-trees have long ago died, and others have grown scraggy or unkempt; the long, well-kept rows of negro quarters have succumbed to time, and the laborers are scattered in fragile huts so as to be convenient to the fields they tend.

The "Great House" itself has shared in these changes. Thirty years of wind and weather have toned down its once cheerful white and green into melancholy dinginess. The roof, despite its shroud of moss and lichens, is so frayed and unsound that one wonders how it contrives to keep out the rain. The former occupants and their fortunes have undergone no less a change, and, if they remain under the old roof-tree, maintain scarcely a shadow of their former state and hospitality.

There is, of course, no lack of snug and thriving homes all through the south, but few of these grand old places, too cumbersome for modern needs, remain, and the old-time southern country-seat is fast becoming a memory.

Kittrell, N. C.

O. W. Blacknall.

"Shongum."—I.

THE Shawangunk Range is a minor branch of the great Appalachian chain. Its most northern point, near Kingston, Ulster County, New York, divides the valley of the Wallkill from the great Rondout valley, and thence, extending south-west, attains in some places a height of 1,800 to 2,000 feet. The Erie Railroad crosses it at Port Jervis, and afterward it is lost in the Alleghanies. Its elevation is so inconsiderable in comparison with the lordly Catskills, which look down upon it across the wide and fertile farm-lands of the valleys, that it was left unnoticed and unknown for many years after the higher mountains had been well explored by summer tourists. But, aside from the historical interest connecting it with the early history of the Dutch settlements along the Hudson, this region is worth consideration for its own sake. Its easy accessibility by rail and river makes the little world thus elevated above the sea-level a ready refuge from the summer heat, and its system of lakes and streams and cascades and forests affords picturesque delights to the artist and unending studies to the botanist.

When the mighty forces of primeval nature uplifted these masses of white sandstone and quartz conglomerate it was done with so steady a hand that the level strata were hardly anywhere tilted; and they stood in parallel lines with gaps between, one mountain wall pushed a little past the next and commanding it—in military phrase—en échelon. Then came the long win-

ter, when the glaciers plowed deep valleys, and on either side piled its broken buttresses and angles against it in the passage, filling its gaps, leveling the tops of its cliffs, smoothing and shaping the spaces inside its outer walls, scooping the abrupt valleys and wearing deep holes in the conglomerate, where now repose the tiny lakes that feed its romantic streams. But its highest points were left unmoved, in level firmness, square and compact as if these were immense forts built for the wars of Titans. And since then, though the storm king at times holds high carnival here, the wear and tear of the elements have been propitious rather than otherwise. The disintegration of the conglomerate gives elements of fertility, and also, when under water, hardens to an imperishable cement, while the sandstone is harder than granite and far more enduring.

Its location gives a wide outlook, for the range is comparatively narrow and isolated, and there are points from whence the view is bounded to the south and east only by the Highlands of North River, the bay at Newburgh being visible, with Storm King frowning above it; or one looks north-east to see the Berkshire Hills of Massachusetts, and north over the levels to where the Green Mountains of Vermont lie in a blue undulating line beneath the farthest clouds. To the west rises the abrupt ascent of the Catskills from the plain, far enough distant for the most exquisite atmospheric effects, and the graceful sweep of these curves toward the south-west opens ever-changing glories of light and color, as the sunshine bathes them or the showers sweep over them.

Our first personal knowledge of the Shawangunk Mountains (commonly called "Shongum") was on a still afternoon, after a morning that had been full of enchanting surprises of light and shadow among the picturesque highlands of the Hudson. A little jaded with travel we had looked over the shoulders of our stage-driver, and without much interest, at the distant uplands, which we were told contained our point of destination, but with which the present direction of our big slow-moving horses seemed to have little to do.

For an hour our road lay through undulating farm-lands in the rich Walkkill valley, and then suddenly turning to the north we drove down a long hill into a deep dell, and straight at the heart of the mountain whose thousand feet of stone seemed to rise like a wall before us, stretching away in unbroken line for miles on either hand. From the depth of the dell where we had entered a grove of Chestnuts, for some distance up this height, the debris piled against it in huge rocks and broken soil, is covered with a forest-growth, hundreds of feet above the trees.

Certainly it required faith in modern engineering to believe anything but eagles' wings would raise us to the top of this perpendicular; but after going down till it reached the lowest point at the foot of this majestic pile, our road began timidly to take hold of its skirts, and climb the way along its side, giving us views of great beauty over the wide valley we had left. Then we reached a break in the wall, and turned sharply away into a pass that was once an Indian trail, and affords the only natural access to the interior of this range for many miles. Here in a few moments a heavy rain struck us, and our horses labored up the steep ascents, straining their great flanks and standing with their legs gathered under them while they took breath a moment on the shelves cut in the road for that purpose, or dragged the coach with the wheels all locked down the steep descents that seemed aimed at the centre of the earth.

When the shower had passed we found ourselves in a fertile region abounding in a great variety of wild growth. One could think that Flora, hiding in these fastnesses, had amused herself in sowing all manner of seeds to make a garden of the wilderness. The Chestnut crowded the Oak, and the red-tipped leaves of the Sassafras peeped between. The Sumach made a lusty growth, and held its green heads high in rocky spaces, vaunting a promise of future brilliancy. Above all towered the Pines, which form the chief glory of the upper plateau to which we had at length ascended. The great rocks amid which our road curved were covered with brown lichens of curious form, while every hollow, every broken place and coign of vantage had its tuft of Fern or its bed of mosses. In the open places bordering the roadway we saw the deep green stiff leaves of the Laurel (*Kalmia latifolia*) bristling against baby Oaks and Chestnuts, whose faces, wet by the late shower, were lifted to us in a kiss of welcome; or the sun glinted from the waxen foliage of the Rhododendron, both *R. maximum* and *R. Catawbiense* growing freely here, and just out of blossom. The fragrant breath of the Spice-bush came to us from some hidden nook, and the beautiful Clematis vitalba threw out its pearls of buds or its feathery blossoms to glorify the rough Raspberry and Barberry bushes lining our way. In other

places there were plantations of Golden-rod contrasting with the brown blooms of the Bindweed (*Calystegia Sepium*) made a thicket of the broken banks whereon were grown in profusion the Blueberry-bushes dear to us from the days of our childhood; for blueberries are everywhere here called huckleberries by the unhappy mortals who have never known the difference between the blueberries of Maine and the sandy abominations sold under their name in the New York markets. But these are the real blueberries, pulpy and juicy and sweet, with the cool, pearly, delicate bloom on the fruit as if frost-fingers had touched them to mark their northern origin. While beneath the trees everywhere grow all varieties of the Pyrola, whose white blossoms now give promise that in autumn their scarlet berries shall chord with October glories, as these berries reflect the blue and gray of summer skies.

Minnewaska, N. Y.

M. H. P.

New or Little-known Plants.

A New Hybrid Rose.

WE have on many occasions alluded to some hybrid Roses which Mr. Jackson Dawson, of the Arnold Arboretum, had produced by using pollen of various hardy sorts upon the Japanese *Rosa multiflora*, which is one of the most beautiful of hardy flowering shrubs. One of these hybrids, in which General Jacqueminot was the male parent, was the subject of an illustration in GARDEN AND FOREST last year (vol. iv., p. 533). It is a vigorous climber, with clusters of semi-double rose-colored and exceedingly fragrant flowers. We reproduce in this number (see p. 461) a photograph of another of these hybrids, in which the single flowers are pure white, with yellow stamens, and borne in clusters after the manner of the seed parent. They are three times as large as the flowers of *Rosa multiflora*, and are fragrant. In this case the pollen parent is the Hybrid Perpetual, Miss Hassard, and the plant has the thorns and foliage of this variety and the half-climbing habit of the Japanese species. Miss Hassard is a Rose which was raised from Marguerite de St. Amande, which is a free grower, with sweet-scented flowers. Marguerite de St. Amande is a seedling of Jules Margottin, and this was probably raised from the old and very hardy La Reine, a Rose introduced fifty years ago, and still well known. Roses of the La Reine type endure more cold than any other class except the descendants of Baronne Prévost, and they include such admirable kinds as Anna de Diesbach, François Michelon and Paul Neyron. The new hybrid, therefore, comes of free-growing and hardy parentage, and, if pedigree counts for anything, it ought to prove one of our sturdiest plants. *Rosa multiflora*, although it has been known for a hundred years, has only in very recent times been introduced to gardens, although its double form crossed with *Rosa Indica* and others has been the origin of the Miniature Cluster or Polyantha Roses which have long been popular. They are not reliably hardy in this country, however, and we have no doubt that the new strain of Roses which is being raised by mingling the blood of *Rosa multiflora* with perfectly hardy sorts will produce many plants which will prove satisfactory and useful.

Cypripedium Daisyæ.

THE flower of the *Cypripedium* reproduced from a photograph on page 463 is from the collection of Mr. H. Graves, of Orange, New Jersey, after whose daughter the plant has been named. It is a hybrid between *C. Lowii* and *C. cænanthum superbum*. The leaves are eight inches long and one and a half broad, bright green and faintly tessellated. The flower-scape is sixteen or more inches long, brown, pubescent, one to three flowered. The sepals are white, pale green through the centre, veined and tinted with carmine, with a few dots of brown at the base, the dorsal one being slightly deepest in color. The petals are long, narrow at base, the inner half a primrose-yellow variegated with purple, the outer half carmine. The lip is similar in shape to that of *C.*

Lowii, being brown, shaded vinous red, paler veined green beneath. The infolded lobes are speckled crimson, and the obcordate staminode is carmine and pale green.

Foreign Correspondence.

London Letter.

OUR garden and flower shows were never brighter in September, though the first frost may deprive us of the Dahlias and of the Begonias, which are being quite gen-

terest was centred in the new hybrid Orchids, exhibited for the first time. Messrs. Veitch, of Chelsea, took a first-class certificate for a beautiful little hybrid, a cross between the scarlet *Sophronitis grandiflora* and *Lælia elegans*, this being the pollen parent. It is named *Sophr-Cattleya Veitchii*, and in growth is intermediate between the parents, but with larger flowers than *Sophr-Cattleya Batemanniana*, being three inches across. The color of the sepals and petals is a bright cinnabar-red, flushed with rose, and of the pointed lip, a rich crimson, with bright yellow interior. It is a plant sure to be valued by orchidists. The other

Fig. 78.—A New Hybrid Rose.—See page 460.

erally relied upon for autumn color after the Pelargoniums have grown rank and flowerless. The exhibition of the Royal Horticultural Society at Westminster on Tuesday was of unusual interest. Besides an extensive collection of brilliant exhibits there were a large number of novelties, especially in florists' flowers and Orchids. The chief in-

hybrids were *Cypripedium* H. Ballantine, between the elegant *C. Fairieanum* and *C. purpuratum*, partaking of the character of both, and as rich in color as *C. purpuratum*. *Lælio-Cattleya Proserpine* is a cross between *C. velutina* and *L. pumila* Dayana, and, though interesting, is not so beautiful as many other hybrid *Cattleyas*. Messrs. Sander,

of St. Albans, sent some extremely choice exhibits; the cream of which was a new *Cattleya*, supposed to be a natural hybrid, but which looks like a variation from *C. aurea*. The flowers are of the same shape, though larger than *C. aurea*, with a broad, spreading, shallow labellum of a splendid amethyst-purple netted with gold, and broad sepals and petals of a delicate blush-white. It is one of the most beautiful *Cattleyas* I have yet seen. It is named *C. Oweniana*. It won a first-class certificate, as did also another *Cattleya*, from Mr. Lee, a Manchester amateur. This was a snow-white variety of *C. speciosissima*, and was named *Sanderiana*. The flower is very large, of faultless shape, and a pure white throughout with the exception of a blotch of lemon-yellow in the throat. In striking contrast was a group of the vivid scarlet *Habenaria militaris*, from Sir Trevor Lawrence. This is a small-growing terrestrial Orchid with long spotted leaves and erect spikes of flowers with trifid labella. No other Orchid that I know, except a *grandiflora*, has such a glowing color as this.

Messrs. Linden showed the new *Arides Augustianum*, with long and dense spikes of small flowers of a pale rose-pink color. This was considered worthy of an award of merit. From Brussels also came some distinct and fine varieties of *Cattleya Acklandiæ*; *maxima*, with a very broad lip, and *guttata*, with heavily spotted sepals, being the finest. Baron Schröder sent a fine erect spike of the new hybrid *Phajus maculato-grandifolius*, raised by Messrs. Veitch. It is among the finest of yellow Orchids, the color of the large flowers being a bright canary-yellow, with lips of chestnut-brown. A large group of *Dendrobium Phalænopsis*, some having spikes carrying two dozen flowers, showed how finely this splendid Orchid can be grown by amateurs who understand the peculiar treatment it likes. *Vanda Sanderiana*, the unique *V. cœrulea*, helped to swell the Orchid display, as did also a pretty group of *V. Kimballiana* from Messrs. Low. This has become an established favorite among orchidists here, as it has no doubt in America. A large number of hybrid *Cypripediums* were shown, but these are becoming so numerous and so much like each other that it is impossible to describe their peculiar characteristics. Some hybrid *Cypripedia* are distinct and handsome, but in many instances these hybrids are much less beautiful than their parents.

Some deliberation was required by the Floral Committee in certificating varieties of *Gladioli* and *Dahlias*, the novelties being so nearly like the older sorts. Among hundreds of spikes of Messrs. Kelway's *Gladioli*, which made a splendid array, only two were found worthy of a special certificate. These were *Numa*, a massive spike of white flaked with rose and tinged with yellow, and *Poetis*, blush-white, flaked with rose and yellow. Messrs. Kelway seem to have reached the climax with the *Gandavensis Gladioli*, but it is said that there will soon be some startling novelties from intercrossing their strain with Lemoine's hardier race, which has, moreover, a greater range and stronger contrasts of rich colors, which have gained for them the popular name of *Butterfly Gladioli*. Among the new *Dahlias* the most remarkable were those from the famous growers at Salisbury, the Messrs. Keynes. These were all of the true Cactus-flowered class, like the original *Cactus Dahlia Juarezi*, not the spurious *Cactus Dahlias* that have been sent out of late years. Of the several shown four were selected for certificates: *Mrs. Bashan*, pink, flushed with yellow; *Kaiserin*, pure chrome-yellow; *Countess of Radnor*, pink, tinged with warm yellow, and *Bertha Mawley*, bright scarlet. These are all first-rate in every respect.

Of the new Burmese Lily (formerly called *Lilium Wallichianum superbum*, now named *L. sulphureum* by Mr. Barker) Messrs. Low had a magnificent group, which showed what a noble Lily this is for decorative effect. The plants ranged from three to five feet high, and each bore from three to five enormous trumpet-shaped flowers of a rich yellow and white. It is not only a fine greenhouse Lily, but proves suitable for outdoor culture in summer. Messrs. Pitcher & Manda sent a fine lot of Lilies, and

remarkable types of the red-striped *L. auratum* (*Rubro vitatum*), which has this year been admirable in the open air at Kew. It is a Lily that attracts everybody, and the finest forms of it are scarcely inferior to the famous *L. Parkmanni*, a glimpse of which we have in flower yearly from Mr. Waterer, at Knap Hill, where it is propagating itself slowly.

That very fine *Canna*, the *Star of '91*, won a first-class certificate, though it was an argued point among the committee as to whether it was as fine as *Madame Crozy*, but as it was considered by the majority to be quite distinct in color it was voted the award. There was a hybrid *Passiflora* between *P. racemosa* and *P. quadrangularis*, which, though interesting, has not much floral merit. A pretty plant was a new seedling *Tacsonia* named *Smythiana*, with scarlet flowers, which we may hear more of later on. Messrs. Veitch had specimens of the hardy *Clerodendron trichotomum*, which, however, did not seem to attract the committee, though it was admitted that every hardy shrub flowering in September was a welcome addition. They also had a fine basket of *Bignonia grandiflora* from the open air, which indicates the favorable warm summer we have had.

Kew.

W. Goldring.

Cultural Department.

Hardy Lilies.

THE list of Lilies that may be called perfectly hardy is a fairly large one, even after eliminating those that may possibly flower once and then disappear. Among these latter class are many very beautiful varieties, including several north-western American species, such as *Lilium parvum*, *L. rubescens* and *L. maritimum*, three species with small bulbs and of dwarf habit which dwindle away under cultivation, even though most tenderly cared for. *L. Columbianum*, *L. Humboldtii* and *L. Washingtonianum* are tall-growing kinds in their native Sierras, and the two last-named produce immense bulbs which often lie dormant a whole year only to put forth a feeble stem that rarely flowers here in the eastern states. Deep planting has been recommended for these Californian Lilies, but it does not make them thrive; indeed, it is necessary to plant them at least twelve inches deep to prevent their premature appearance above the ground where they are cut off by late frosts in spring. Evidently there are some necessary conditions which we do not comprehend or cannot give, to make such lovely plants at home here. For the amateur, therefore, it is safe advice to plant very few of the six kinds named above. Of other Lilies that I have hitherto failed to keep, *L. tenuifolium*, a Siberian species, flowers once and then dies, though it is the easiest of all Lilies to raise from seed, but *L. pomponium* is so much superior to it in every way that it need not be further considered. *L. Pyrenaicum*, which should be perfectly hardy here, has always failed with me, the bulbs decaying at their base and eventually disappearing, but at its best *L. Pyrenaicum* would be an undesirable kind to many on account of its heavy odor. *L. Martagon*, the typical *Turks-cap Lily*, with its white variety and the so-called black variety, *Dalmaticum*, are sometimes grown successfully in the United States, though I have never managed to keep them. It is said that they prefer a poor, stony soil. If they could be grown, the three kinds of *L. Martagon* would form an interesting group, and they flower early in the year. It is dismal work to have to record so many impossibilities, but it must be remembered that I am simply recording my own experience. Other persons may succeed with them, but it would be safe advice to novices to make trials of other kinds in preference at the outset. It is with a sigh that I include *L. Szovitsianum* with the foregoing, for, to my mind, it is the most beautiful of all Lilies, though not the most gorgeous, but the beautiful canary-yellow flowers with their deep red base never greeted my eyes but once. Their beauty is not forgotten, nor can I forget that out of a dozen bulbs but one flowered, and that was the first year after planting. The next year no bulbs were there to flower.

And now, as we consider the kinds that may be planted with hope, it must be remembered at the beginning that it is difficult to state just when they flower, because, in every locality the time would vary. *L. Hansoni* with me has always flowered first, and it is a beautiful Lily; the petals are thick, almost leather-like in texture, bright orange-yellow, with red spots; the plant is vigorous and free-blooming. *L. pomponium*, as stated before, should be in every garden, instead of *L. tenui-*

folium, because its flowers are of the same bright orange-red, and there are many on a stem varying in number with vigor of the plant. The flowers appear early, too, and are pleasantly fragrant. *L. croceum* is the old-fashioned orange Lily, and is a good kind to plant where a permanent group is wanted. It is usually about three feet high when in bloom with umbels of erect orange-red flowers. *L. elegans* is similar in habit but not so tall when fully developed; the flowers are similar in color but vary in different varieties, of which there are many in catalogues, but the mixed bulbs, as grown by the Dutch, give a pleasing range of color and are exceedingly cheap—in Holland. It should be stated that *L. elegans* is often grown under the name of *L. Thunbergianum*, but *L. elegans* is the older name. The dwarf habit of this species makes it valuable for margins of Lily-beds or borders where shrubs are planted. All are familiar with *L. candidum*, the Madonna Lily; it is perfectly hardy, but we grow it in pots, the same bulbs year after year, for piazza decoration in summer, and the bulbs improve in size. They are rested after flowering and repotted in July, just before growth commences, for in fall this species has green leaves all winter. *L. Harrisii*, the Easter Lily, and *L. longiflorum* are both hardy in sheltered situations with a covering of leaves in winter. The tendency with these two kinds is to start to grow the first year in fall, but after a year or two they forget all about it and come on naturally in spring. The Tiger Lilies are well known as hardy, but the older variety should only be grown to complete a collection, as the kind known as *L. tigrinum splendens* is so much superior to it. The double variety is good for its durability when in bloom, though many do not admire the double flowers. *L. excelsum* of catalogues, more correctly *L. testaceum*, has flowers of a different color from that of any other Lily. This is a light brown or buff, and it is very distinct and ornamental. This Lily should always be planted in a collection, though it sometimes deteriorates in rich soil. In habit the plant resembles *L. candidum*. *L. Chalcedonicum*, the scarlet Turk's-cap Lily, is a native of Greece and is somewhat tender, but in favored localities it should succeed and produce its bright scarlet flowers freely enough.

Of the Japan Lilies, *L. auratum* is, perhaps, the best known, and little needs to be said of it except that I never knew any one to grow the same bulbs long in such health and strength as we receive them in from Japan. The bulbs are cheap, however, and are sure to pay for themselves the first year after planting. There are many varieties of *L. speciosum* (often called *L. lancifolium*), but the best kind is that known as *Rubrum*, which we get from Japan direct, the Dutch variety being much inferior to it in color, and may be considered as being the typical *L. speciosum*. Of white-flowered forms, *Album præcox* is the best, because it always flowers early. The old white kind flowers later, and is sometimes killed by frost while in bud. This section of the Lily family includes varieties among the handsomest of the genus. They are perfectly hardy, increase under cultivation, and are indispensable to the hardy-flower garden. There are other varieties of *L. speciosum* which are but slight variations from the two named, which are the best of the section. *L. Batemannæ* should be named in connection with *L. tigrinum*, which it resembles closely, except that the flowers are not spotted, but are of a clear apricot color, and desirable for that reason. The dwarf *L. Wallacei* has also flowers of a similar color, but does not exceed eighteen inches in height. By some it is considered but a variety of *L. elegans*. The bulbs are always small, but they usually flower freely and increase rapidly. *L. Browni* is a rare variety, with

flowers similar in shape to *L. Harrisii*, but larger, white inside, and purplish brown outside the petals. It is exceedingly fragrant, hardy, but rather expensive, but when once planted in suitable soil does not die out. *L. Kramerii* is a species possessing a refined beauty peculiar to itself, the flowers being of a delicate rosy pink, and borne usually one on a slender stalk. This kind requires careful nursing to induce it to do well, but it is possible to grow and flower it in sheltered positions.

Lilium pardalinum is the only native western Lily that will thrive in the east, but it grows so cheerfully and luxuriantly that it really seems to be making an honest effort to atone for the bad behavior of its companions of the Sierra Nevada. With us it is as free as *L. superbum*, which it resembles strongly, although it flowers earlier. All of the species found in the eastern states, *L. Canadense* and its varieties, *Rubrum* and *Flavum*, *L. superbum* and *L. Philadelphicum* thrive well when planted in the garden, but the last-named should be planted in a dry soil not more than three inches deep. When planted the usual depth *L. Philadelphicum* will surely perish. Of the noble Himalayan *L. giganteum*, I cannot record any success, and have never seen it in bloom, but Mr. Ellwanger's experience with it, as recorded in GARDEN AND FOREST, ought to encourage others, now that we know it can be grown. The bulbs are very large, and often remain dormant a year after

planting, but should start to grow the second year, although with me they did not. Of another East Indian Lily, *L. Wallichianum superbum*, usually considered tender, it is worthy of remark that last June, in Mr. Hunnewell's gardens at Wellesley, I saw a clump that had been outdoors in the open ground all winter, and the growth was vigorous, and promised well for bloom. If Wallich's Lily proves hardy it will be a great addition to the Lily-border, for, under pot-culture, it usually languishes. This and its first cost has had much to do with its rarity in gardens.

Lilies generally do not require a rich soil, in the usual acceptance of the phrase, but a soil rich in decayed vegetable matter is eminently suitable. Hence a compost of good loam and decayed leaf-mould made porous is what is desired. There are some kinds, such as *L. tigrinum*, *L. speciosum*, *L. candidum* and *L. Harrisii*, that like manure both in

Fig. 79.—*Cyripedium Daisyæ*.—See page 460.

the soil and in the water given, but these are the most vigorous of all Lilies, and the same would not suit any of the more delicate species. The depth to plant Lilies should vary with the size of the matured bulbs. All the larger kinds may be planted the depth of the spade, about nine or ten inches, bearing in mind that the roots that do the most of the work are produced up the stalk between the bulb and surface of the sod, and if the bulb rests on the subsoil it does not matter, so long as the top soil is right. When manure is applied to the soil the bulbs should first be covered with soil free from it, or decay may be brought on by contact. The richer soil should be used for the stem-roots to feed upon. The ideal position for a Lily-bed is among Rhododendrons. Where these will thrive the Lilies will, the taller kinds being used to come up through them, and the dwarf ones near the margin of the beds. The leaves used to mulch the Rhododendrons in winter are a fine protection for the Lily-bulbs, and afford when decayed all the needful fertilizer, while the shrubs shade the surface of the soil and keep it cool and moist in summer, which is a great advantage. A bare surface soil, which radiates heat in hot weather, turns many of the leaves of Lilies yellow, and causes premature ripening of the stems. In common with all other cultivated plants, the Lily has a disease of its own. Some collections, to

my knowledge, have been completely exterminated by its ravages. It attacked our Lilies this season. It remains to be seen what the results will be next year. Rusty yellow patches on the stems and leaves tell of the work going on, and soon the stalk dies off, and the bulb is weakened for next year. I have had no opportunity for comparison, but the symptoms are unmistakable. Apart from this disease, there is no reason why we do not see more Lilies grown in gardens. Enough are forced in one year for Easter to plant bulbs in every garden in the United States, and yet how seldom do we see this family represented, except, perhaps, by a clump of Tiger-lilies that have been undisturbed for a generation, and yet live to flower and plead for attention and encouragement.

South Lancaster, Mass.

Autumn-blooming Perennial Plants.

CHRYSANTHEMUMS have absorbed so large a portion of the attention of gardeners in recent years that other autumn-flowering perennials have suffered some neglect, and Chrysanthemums are rapidly becoming plants for the greenhouse exclusively. The early sorts give little promise of being out-of-door bloomers, if one may judge from a large collection of the new French strains seen a few days since, which seemed scarcely as forward as the old Madame Desgranges. For a garden of narrow limits the selection of plants for flowers at this season requires more care than for those of spring and summer, as at this time many plants are apt to become rank in growth—weedy, in fact. In selecting plants for conspicuous positions care should be given to obtain those with good foliage, as the weather is at this time very trying to all leaves. The popular Sunflowers are usually quite defective in this respect, and quickly become unsightly. For a suitable position, however, they are, of course, among the attractive flowers of the season. An excellent succession of these is *Helianthus rigidus*, the double-flowered *H. multiflorus*, *H. lætiflorus*, *H. orgyalis* and *H. Maximiliani*, the two latter being especially graceful in foliage, and *H. Maximiliani* is in flower long after the first frosts.

Of the more modest flowers of the season, *Anemone Japonica alba* is easily the most charming, and is usually entirely satisfactory if the position is somewhat moist and not too open. *Delphinium Sinense* seems to me scarcely less beautiful in either of its three colors, white, pink and a heavenly blue. It has a very neat habit, of moderate growth and a long season of bloom. Messrs. Pitcher & Manda had it in flower in November last year in the open nursery. This species should be very popular when better known. The autumnal Monk's-hood (*Aconitum autumnale*) is a plant of very trim habit, two to three feet high, with glistening dark green leaves and abundant large hooded flowers of a pleasing purple. *Stokesia cyanea* has flowers of a lighter purple, like a full-petaled single Aster, though the foliage is not specially attractive. This plant is probably not hardy here without some protection, which is also a drawback to the cultivation of the Torch-lilies, or *Kniphofias*, which have been so much improved, especially by Herr Max Leichtlin, in recent years. There seem about two-score varieties available, these varying in habit and coloring of flowers; few are hardy without protection from wet and severest frost. No good garden is complete without some varieties of these plants, ornamental in foliage and flower. Of the most common varieties *K. corallina* is most likely to give general satisfaction. It is a dwarf kind, of very thrifty growth, and gives a succession of bright torches until frost. They winter without harm in a frame or cellar.

Pyrethrum uliginosum, with its Chrysanthemum-like habit and white daisy-like flowers, is now in season, and likely to prove satisfactory. It should have a sheltered place, where wind will not thresh the fair flowers, which are thin of petal. Another fall daisy is *Chrysanthemum lacustre*, a plant of coarser habit, proof against severe weather, and somewhat of the wilding order. The best composites of the season are the perennial Asters, the varieties of which are so plentiful in our American fields at this season. No plants are more satisfactory in the garden than the best of the Asters, with their bright multitude of flowers. A standard collection of the family, correctly named, in some one of our botanic gardens would be of real interest. At present it is practically impossible to secure even a small collection from two nurserymen which shall be named alike. Were there more room in my garden I think probably there would be added some fine forms of Golden-rod, full as the fields are of them. *Solidago cæsia*, with long wand-like stems and clustered axillary flowers, seems to be the perfection of grace and brightness.

A sowing of Iceland Poppies made early in the year is now flowering freely and vying with the brightest flowers in the

garden. Scarcely less bright is the well-known *Plumbago Lar-pente*, with its blue flowers and foliage, which is taking on bright autumnal tints. *Sedum spectabile* adds color in spots which prove too dry for other plants. *Gaillardia grandiflora* is, perhaps, not strictly a fall flower, but nothing but a hard frost will give a pause to its floral succession. Among bulbous plants, the flowers of the season are from varieties of *Colchicum*, *Crocuses* and *Cyclamen*. *Cyclamen Europeum album*, now showing pure white flowers, would be much more attractive with leaves, but at present there are none. *Cyclamens* are difficult bulbs to establish in the open, and I have not yet discovered why they live through one winter and are pulped the next. The garden is made interesting and expensive by these little experiments. Plants with magenta-colored flowers are not long-lived in my garden, but it seems worth while to make an exception in favor of *Lespedeza Sieboldi*, which has such a graceful habit, with its pendulous branches covered at this time with a myriad of pea-shaped flowers. Roses give such a plentiful daily crop of buds at this season that it seems ungrateful in talking of hardy plants not to mention them, though what I know of them may be summed up very shortly. A man may have Roses in his heart, as the well-known saying goes, but if he wants them in his garden he must set his plants in a good, deep compost (two feet not being too much), rich with manure and bone-meal. *Gloire de Dijon* and *La France*, both of which are hardy with me with no protection, give decidedly more flowers than other varieties which have been grown here.

With all its wealth of showy flowers the September garden seems to me the least interesting one of the year. Crops are a mere detail, not always essential to the enjoyment of a plant. Human beings, as children, are often more interesting to their guardians, filled as they are with wonderful potentialities, than when in full development of maturity. And plants, new or old, in their early growth give pleasurable anticipations which are not always realized. Again, we are in this latitude never free from danger of killing frosts after this date, and garden operations must be shaped with this contingency in view. Then around us is the glamour of the glorious American autumn, tinging the fields and ripening leaves with a wealth of colors overpowering the brightest garden. Seen under a declining sun at this season our Jersey meadows show broad, harmonious and exquisite shadings of color which no expert in bedding-out can hope to rival. When one has perceptions open to these impressions the mere enclosed garden is at this season rather commonplace.

Elizabeth, N. J.

J. N. Gerard.

Cool-house Ferns.

AMONG the many fine Ferns that may be successfully grown in a cool-house, that is, in a temperature forty-five to fifty degrees during the winter, there are few superior to *Hypolepis distans*, an evergreen of much elegance and free growth. This Fern makes a mass of dark green bipinnate fronds about a foot in length; these are finely divided and serrated and thrown up from a creeping rhizome. Like many other Ferns of creeping habit, this species does not require a great depth of soil, and pan culture is therefore advisable. Planted out on a rock-work it is equally at home.

Pteris scaberula is a fine companion plant for *Hypolepis distans*, and thrives under similar conditions. The fronds of this species are also finely cut, lanceolate in general outline and light green in color, and they are produced from slender rhizomes. This admirable Fern is partly deciduous, and is, consequently, likely to become rather rusty-looking during late winter and early spring. But the beauty of the young growth fully repays for any previous shabbiness, and it is well worth a place in any conservatory.

An unusually pretty Fern, and also an uncommon one, is *Athyrium Goringianum pictum*, a variety introduced from Japan some years ago. It has long pendulous fronds, the stems of which are pinkish or red, and the pinnæ on each side of the midrib are variegated with a lighter shade of green, thus making a light stripe down the centre of each leaf. This variety will grow nicely in light loam, if proper attention is paid to the drainage of the pots. The plant is entirely deciduous, and should be stored away under a bench when the fronds die down and watered often enough to keep the soil moist.

Adiantum Capillus-veneris magnificum is one of the best forms of the common Maidenhair, and can be grown into a very pretty specimen, besides having good lasting qualities when used in cut-flower work. This variety has particularly large pinnæ, possibly the largest in the *Capillus-veneris* sec-

tion, and the fronds are gracefully arched. *Todea Africana* is another very fine cool-house species. It makes a short, stout trunk as the plant attains age, from which are thrown up large bipinnate fronds. These are of strong texture and the pinules deeply serrated on the margin, the surface of the fronds being dark green and glossy. It makes a particularly handsome specimen when well grown. It is a strong rooting species and requires an abundance of water to keep it in good condition.

Cyrtomium falcatum is one of the brightest-looking Ferns in a collection; its pinnate fronds have a fresh green color and a high gloss. It is almost hardy, and is quite so in many parts of England, where it is much used for planting in outdoor ferneries, though under such conditions it is almost deciduous, while it retains its foliage in good condition during the winter when grown under glass. *C. caryotidum* is similar to *C. falcatum* in form, but is very different in color. The fronds are much lighter and they are also thinner in texture, and it is less glossy. It is not as hardy, but makes a pretty plant and is readily raised from spores. *Brainea insignis* is a very handsome Chinese species of moderate growth and arborescent habit; the pinnate fronds reach a length of two and a half to three feet. The pinnæ are lanceolate in shape, with serrated edges, and the young fronds are pinkish, gradually turning to bronze and later to green. *Brainea* is a monotypic genus and continues somewhat rare, though a noticeably handsome species.

Among the smaller Ferns, several of the Pellæas are excellent; they are useful for pot or basket culture or for planting in a rockery. *P. rotundifolia* is good, the nearly round pinnæ strung along each side of the dark brown rachis having a very light and graceful effect; a native species from the far west, *P. bella*, is also beautiful, growing to a height of six or eight inches only. Other members of this genus valuable for the cool-house are *P. calomelanos*, *P. brachyptera* and *P. flexuosa*.

Tomato Diseases.

TOMATO plants have been troubled with fungi this season, and consumers are complaining of the high price and poor quality of the fruit, while the tomato growers are lamenting the short crop. In some localities the young plants were destroyed or much weakened by the bacterial disease known as the Southern Tomato Blight. This has been followed by the old leaf-enemy, *Cladosporium fulvum*, which produces a light brown, almost olive, mold upon the under side of the foliage. Plants with much of this fungus usually bear inferior fruit, and frequently the same enemy appears upon the fruit while it is green and less than half-grown; the blossom end turns brown and decay sets in.

The newest enemy, and one of no small importance, is an anthracnose, *Colletotrichum Lycopersici*, which was first observed by Professor Chester, at the Delaware Experiment Station, last season, and described by him in the *Torrey Bulletin* for last December. This fungus produces sunken spots in the fruit, which become soft and dark. It quickly destroys the Tomato, and for this reason and by its peculiar appearance it is usually recognized as different from any other known Tomato rot. Several times my attention has been called to the ravages of this parasite by growers who observed that it was a new enemy.

The same fungus is to be found upon the foliage, when it causes brown, irregular spots. At this time, when the fruit is well advanced and frosts are expected daily, there is little or nothing to be done, except to see that the vines are finally gathered and burned. There is no question about the contagiousness of the anthracnose. The spores are numerous, and should be destroyed at the close of the season, if not before.

Hardy Cyclamens.

MR. EDWARD WHITTALL, writing to the *Mayflower* on the Cyclamens of Asia Minor, says:

The Cyclamen is another plant which has proved of interest to me as a collector. A few years back I believed that it was represented in Asia Minor by *C. Europæum* alone and I was accordingly well pleased to find that many varieties existed. *C. Europæum*, as I have no doubt your readers well know, blooms before any of its beautiful ivy-like leaves appear above ground. All the hedges around Smyrna are full of it, and with the first dews of September its pretty pink-white flowers appear to remind us that autumn is nigh and we have done

once again with our hot, dry summer. If we could cap the remarkably beautiful foliage of *C. Europæum* with its numerous and large blooms, what a pretty plant would be the result.

On the sea-coast between the promontory opposite the Island of Chios and the headlands opposite that of Rhodes, I found what I believe must be *C. macropus*. The foliage of this variety, though not so massive as the first-mentioned, is prettily marbled, in some cases almost silver-white, which, joined to numerous and pretty pink-white flowers, makes of it an acceptable plant for house-decoration from December to March. It has, therefore, the merit of being easily bloomed a month or so before the beautiful English hybrids now so much under cultivation. This variety is called in Smyrna the large Rhodian, as it was first brought from that island, where it grows abundantly.

Following up this clue, one of my men came across what I should say is *C. Ibericum*, at the foot of the Anti Taurus, Boulghar dagh and Allah dagh ranges, a few miles from the town of Adana. The leaves of this plant are smaller and not so pretty as in the large Rhodian, but the blooms, which are purple-crimson, with a very dark eye, make it a good acquisition. It flowers in March.

My prettiest finds, however, date from 1891, viz., two dwarf Cyclamens. The first, like *C. Europæum*, flowers in autumn, throwing up its whitish pink blooms almost before its pretty marbled leaves. The bulbs rarely exceed an inch and a half across, and when taken out of the soil are of a glossy flesh-color; quite distinct from any others of the genus found in these parts. The leaves are small, barely three-fourths of an inch across.

The second dwarf I consider a gem for rockeries. The bulb, like that of the first, is small, even smaller, flesh-colored and glossy. The leaves are prettily marbled, and more delicate than in the first. They grow so thickly on the plant that in the numerous specimens I grew this year I had not one plant in which the foliage measured more than four inches in diameter. This was surmounted by a numerous set of very large blooms, as compared to the foliage, of a dark red or purple with an almost black eye. I have seen Coum and other dwarf varieties, but I believe none come up to this miniature Cyclamen, either in size or floriferousness. Both these dwarfs were found on the western spurs of the Taurus, above the towns of Adalia (the ancient Attalia) and Phœnicia, and as they were discovered peering out of the snow at an altitude of 3,000 to 4,000 feet they will probably prove hardy.

Correspondence.

Early Autumn near Cape Cod.

To the Editor of GARDEN AND FOREST:

Sir,—I should much rather write myself down as living on Cape Cod than near it, for there is a distinctiveness, not to say distinction, in its name, a share in which all its neighbors covet. Every one knows where Cape Cod is, and thinks he knows what it is, although accurate knowledge on this latter point is, as a fact, extremely rare, while to say that one lives on the western shore of Buzzard's Bay conveys a very vague idea to most persons of other than New England birth.

However, though we are only three miles to the westward of the Wareham River, on the eastern bank of which Cape Cod begins, no one worthy to speak to the readers of GARDEN AND FOREST could claim to belong to "the Cape." For its nominal beginning is a true geographical beginning, and this means a distinct botanical beginning, or, more exactly, a distinct botanical leaving off. Everything that grows on Cape Cod grows here, from Cranberries to Pitch Pines. But many things grow here which do not grow beyond the Wareham River—White Pines, for instance, in profusion. And many other things flourish here which just cling to existence there, so that the whole aspect of our woodlands and road-sides is different; and as one drives still further to the westward, the difference grows ever more strongly accentuated, so that even five or six miles from the shores of the bay one can hardly believe that the sandy, heathy, boggy, rough-and-tumble stretch of the Cape country is covered by the same sky which covers these verdant rolling meadows, the sturdy Oaks and Maples and White Pines of the woodland, and the great Poplars and Locusts by the cottage-doors.

So, we think, we are repaid for not belonging to the Cape by the variety which our daily excursions can compass. The Cape is delightful, but it is all of a piece, and those who live on it cannot easily go elsewhere. But we can go to the Cape after dinner and be back to tea, and the next day can go to our pas-

toral inland country in an equally brief space of time. Nor do we always think that we must go far in either direction, for even the roads nearest about us offer perpetual variety, now crossing salt-marshes and causeways over rippling arms of water; now threading tall Pine-groves, and now Oak-thickets, to bring us out on modest elevations, which we are pleased to call cliffs, where, suddenly, the wide azure expanse of the bay is seen beneath our feet; now taking us between hay-fields and small fruit-farms, where the houses are prettily gray or white and the barns are bigger than the houses; and, again, leading us through miles of narrow roads, where woods of some twenty years' growth come close to the carriage-wheels, the boughs meet overhead, and the grass grows tall between the three ruts worn by the never frequent, but never altogether failing passage of the typical vehicles of the country—the shakily, faded buggy and the black-hooded, four-seated carryall, each drawn by its single horse. Two-horse conveyances cannot comfortably penetrate these wood-roads, although for a one-horse vehicle they offer very good driving, the sandy soil of the Cape only appearing here and there in very brief stretches. No visitor should bring his own one-horse vehicle to this part of the world, but should depend upon those he will find awaiting him. Our axles are so wide that an imported carriage does not "track," and the difference between driving in such a one and in one which does track is the difference between entire comfort and an exasperating tilt and joggle.

Of course, it is in the mountain regions of central and northern New England that the colors of the American autumn show in the grandest and most amazing way. But our vegetation "turns" very beautifully; and it reveals its beauty, so to say, in a much more intimate fashion. The finest autumnal features of an inland scene are distant stretches of parti-colored hill-side, tall, broken masses of variegated forest in the middle distances, and, sprinkled about in the nearer meadows, superb single examples of flaming red or yellow or purple trees. But we have no hill-sides; when we see a mass of woods in the middle distance it is low and draws a nearly straight line across the horizon; and, in our most characteristic drives, the trees are small, and one sees them very close at hand, crowded beside us, and their boughs close above our heads. Here and there we get fine open views of meadows and marshes bounded by woodland or sea. But they are all flat views, and, as a rule, there are few isolated large trees. The colors in autumn lie in low far-extending level masses, or, when we thread the forest-roads, strike the eye as a perpetual succession of details, rather than as broad effects. Roads such as these are called, I believe, "green-ribbon roads" in some parts of New England. Ours are certainly ribbon-like, perpetually and gracefully meandering with never the smallest stretch of straightness, and in summer they have a green all their own, for no inland light brings out the keenest emerald tints possible to foliage as does the salt-spangled light of these sea-shore parts. But when we look along them in autumn we feel as though we had put an immense kaleidoscope to our eye, so many are the colors they assume, and so impossibly vivid each one seems.

Of course, it is not in the first half of September, not until October, that, in these mild regions, one sees autumn in a very brilliant guise. But the beginning of the red and yellow season has a special charm of its own. Autumn is setting her palette, trying her effects with little streaks and spots and splashes, indicating what she means to do, sketching in her color-scheme; and every one knows that a great artist's sketches have a peculiar value to the understanding eye. A tricky and willful sprite is this particular great artist, in those youthful days when her Christian name has not been changed from "Early" to "Late." There seems no reason in her work, although everything she does rhymes delightfully with the next thing. I pity any scientific student who should come to our woods in mid-September, trying to unravel why our foliage "turns." Neither frost, nor sun, nor moisture, nor dryness can be credited with any distinct influence; little can be laid to the account of family traits when tree is compared with tree; nor does soil or situation seem to have a discernible effect upon the gay beginning of the masquerade.

We may say, in a rough sense, that the Tupelos turn first. But some of them turned in August, and some have not yet begun to turn, while some are russet and others are redder than scarlet. And a green one may stand close beside the brightest red one, or one bough may be scarlet while all the others are emerald still. But even the Tupelos are not so individually willful as the Maples. They are all Scarlet Maples by name (the Sugar Maple does not grow with us), but they are not all equally scarlet by nature; or, at least, they do not

all reveal this nature at the same time or in the same way. This year they began to enliven themselves unusually early—a week or more ago many of the smaller ones were already vivid. But I have never noted a year when they enlivened themselves in so fragmentary and fantastic a fashion. It is hard, as yet, to find an example which is red all over. I passed a wide swamp the other day which was surrounded by hundreds of them and thickly beset with others, all hardly more than saplings, gracefully tall and slender. Every one of them, I think, showed some brilliant red; but not one of them, as far as I could see, had more than one or two red boughs. It was not as though each tree had assumed a new garment; it was as though each had flung out a bold banner of its own. Often, in the narrow woodland roads, one comes upon a Maple with not a whole bough, but merely the end of a bough flaming; or not the whole end, but just a couple of swinging leaves. In my drive to-day I came upon a good-sized symmetrical specimen, still perfectly fresh and green, with one single scarlet leaf hung out over the roadway; and immediately beyond it was another with only half a leaf tinted, the line between green and red being as neatly drawn as though by a painter's brush. And as the Maples are behaving, just so are the Scarlet Oaks, while their big brothers, the White Oaks, give no sign that they know the summer is past.

Where the roads skirt the salt-marshes splendid effects of color may already be seen, although these are less vivid than those which will soon follow. The marshes (we call them "ma'shes" here, and so, says an English friend, are they called in South Devon) are not orange-colored yet, but they are a fine dullish yellow, streaked with green and brown, and here and there accented by big patches and ribbons of a blood-like deep red. From a distance the plant which gives this remarkable color looks like some species of *Salicornia*, but I have never been able to get near enough on the yielding soil to see it distinctly. Around these marshes the woods are still chiefly green. No brown tones yet appear, and of yellow tones only the dull neutral tints of the little Birches. But a splash of scarlet shows occasionally where a Maple or Tupelo stands with its foot in the wet.

Where the roads go beneath tall Pine-groves not a sign or symbol of autumn appears. The sparse growths beneath are as freshly verdant as the soft swirling canopy of needles above. But the open roadsides are gay, for we pride ourselves on our variety in shrubs and vines, and these turn early; and, moreover, the Asters and Golden-rods are still at their finest. No withered grayish plumes stand for the Golden-rod yet, but along the shores the thick-leaved maritime species is in perfection, and on drier spots other tall or low paniculated kinds, and the softer, more poetic flat-topped masses of the corymbose species. The *Vacciniums*, which later will spread a carpet of glory along the roadsides and through the woodland glades, are already, some of them, bronzed and some of them red. Here and there a *Clethra* has turned bronze-like too. Once in a while we come upon a little *Sassafras* whose mitten-like leaves are yellow and red in spots like a particularly speckled apple. Now and then, like a flash of flame, a thin garland of Virginia Creeper encircles a Pine-tree trunk; near it flaunts a mass of Poison Ivy, and, further on, a streamer of *Smilax* tries to make us believe it is a Virginia Creeper too. Sometimes, lying low beside the road, beneath an arboreal canopy still entirely green, there is a mass of varied tangled color enchanting to behold; and, again, the undergrowth is as green as the trees, except for tiny spikes and spots of russet and scarlet.

The eye which can appreciate accents as well as broad effects, which loves details as well as masses, and which can be delighted by a little colored leaf as well as by a huge colored tree, finds infinite satisfaction in our country in these early autumn days. And what a sky covers this diversified panorama of simple beauties! People who live among the hills must do without real horizons. They never know what it is to see the edge of their world in every direction, and to know what the sun's rays are about in all quarters of the sky. They never see a sunset as we see it here all around the margin of the heavens. This is particularly the month for sunsets, and we usually have four of them every night. There will be a crimson one flaring in the west and a rosy one blushing in the east; one with masses of dark purple clouds lying over a purple sea to the southward, and a colder, purer, even more enchanting one in the north, pale green as to its sky, palest lavender as to its clouds. No mountain region can do this for you, and you must come to our individual little corner of the world, just under the heel of Cape Cod, to know exactly what you miss by living in the mountain.

Marion, Mass.

M. G. Van Rensselaer.

Scab-proof Apples.

To the Editor of GARDEN AND FOREST:

Sir,—In the line of Professor Bailey's statements (p. 442) it is deplorably true that in Wisconsin this season none of our market apples are without injury from scab. Never were prospects finer at blooming-time for a bountiful harvest of apples than last spring, but in the latter part of June, the scab fungus, stimulated no doubt by the cool, wet weather, spread over our orchards in a surprisingly short time, causing almost a total ruin of the prospective crop. The few apples that remained on the trees are so badly scabbed that not many of the samples shown at the state fair this year were unblemished.

But in this season of almost omnipresent scab, Mr. George J. Kellogg, of Janesville, Wisconsin, exhibited a well-laden branch of a new seedling Apple, which, though grown in an orchard in which the profuse bloom of last spring was almost completely blasted by the scourge, had developed a fine crop of apples that were as free from scab-marks as if no germs of this disease had ever alighted upon them—a pleasing evidence that scab-proof apples may not be among the impossibilities.

The "squirt-gun" has, no doubt, come to stay, but I have little hope that in seasons when we most need its help, that is when profuse showers are frequent in the month of June, it will ever be able to give us fair fruit. We must supplement it by systematic breeding from scab-resistant varieties before we shall escape damage from this most serious scourge of the orchard.

Recent Publications.

Garden Design and Architects' Gardens. By W. Robinson, F. L. S. London: John Murray, 1892.

The illustrations in this little book are in themselves of sufficient interest and value to justify its publication, and the author himself seems to consider them the essential part of the work, if we are to judge from the sub-title, which states that it is his purpose "to show, by actual examples from British gardens, that clipping and aligning trees to make them 'harmonize' with architecture is barbarous, needless and inartistic." A proposition of this sort needs little argument to substantiate it, and little argument will the reader find. Mr. Robinson's work, in form, is principally a review of *The Formal Garden in England*, by Bromfield and Thomas, with a short additional criticism of *Seddings' Garden Craft, Old and New*. In reality it is an impassioned protest against some of the false doctrine of these two works—and plenty of false doctrine do they set forth.

The first of these books has been already reviewed in these columns. It is rather an attractive little treatise, and, begging Mr. Robinson's pardon, it contains many pretty and interesting pictures. The authors have our sympathy, too, so far as they show a preference for old-fashioned, geometrical planting over much of the formless fussiness of many modern gardens. The fundamental error of the authors is, that they appear never to have seen a good example of grounds that have been treated "naturally" and at the same time artistically, or if they have seen such places they do not appreciate their beauty. Indeed, there is nothing in the book to show that the authors have any feeling for natural beauty or any intelligent appreciation of scenery. It is charitable to assume that they are quite destitute of the original faculty to which the beauty of scenery appeals, and the mistakes of their book are exactly of the kind which would be made by a man with no ear for music, if he should write a criticism of Beethoven's Fifth Symphony. The lack of this special sense will account for the assertion that landscape-gardening is essentially the abandonment of everything like design. They can see no "order" or "balance" except in the repetition of architectural lines and angles. It is not strange, therefore, that they should fall back on etymology and insist that the essential feature of a garden should be a strong boundary line.

Mr. Robinson's pictures need no additional text to show how delightful to the eye the so-called natural style of planting can be made, even in connection with buildings, whether stately or humble. And the text adds little to the force of the illustrations. Mr. Robinson's language is fervid, and at times perfervid, but a display of feeling does not always aid an argument. As has been already said, however, little argument is needed to demonstrate the errors into which the two young architects fell when they essayed to prove that one kind of garden was essentially good, and all others essentially bad. The fact is, that there are gardens of a good many kinds, and gardens made to fulfill a good many different purposes. Mr.

Robinson himself is the able advocate of a garden whose "true use and first reason is to keep and grow plants which are not in our woods, and are mostly from other countries than our own." But, then, there are gardens whose beauty is of the very highest type which were not designed with any such motive.

Bulletin 43 of the Cornell University Experiment Station treats of certain "Troubles of Winter Tomatoes," two of which are so obscure in their ways that growers often fail to recognize them until the crop is ruined. One known as the winter-blight was first described in GARDEN AND FOREST last April (page 175) by Mr. E. G. Lodeman. The disease first appeared in the winter of 1890-91, when only a few plants were affected, and as they had borne one crop it was thought that they were simply worn out. It became necessary, however, to carry a dozen plants over the summer, and these were introduced into the house when the forcing season opened last October. From this stock trouble again spread, and in six or eight weeks it had become serious, and there was no longer any doubt but that a specific disease had to be contended with. The first indication of the trouble is the dwarfing and fading of the leaves and the appearance of ill-defined yellowish spots, which soon become dark and the leaf curls, with its edges drawn downward, so as to give the plant a wilted look. This injury causes the plant to dwindle, fruit-production is lessened, and in some cases the plant dies outright. The indications point to a bacterial origin for the disease, but this is not certain, and no remedy has been found for it as yet. The disease travels from plant to plant when they stand in separate boxes, even when their tops do not touch. Experiments lead to the conclusion that the best treatment for this blight is to remove all diseased plants at once, and if it becomes serious, to remove all the plants and soil in the house and start anew. The experiments, too, emphasize the importance of starting with new plants and fresh soil every autumn. When once the disease gets in a house it seems fatal to success in forcing Tomatoes.

The common blight which is associated with Tomatoes, *Cladosporium fulvum*, appears as cinnamon-brown spots on the under surface of the leaves. This fungus, however, is rarely serious. It is apt to appear in late winter or early spring, and often not until after the crop is nearly harvested. In such cases the old plants should be burned as soon as the last fruit is off. If it appears earlier, spraying with the ammoniacal carbonate of copper is to be recommended.

Another serious injury of winter Tomatoes is the root-gall which comes from nematodes. Many plants like Geraniums, Coleus, etc., are subject to the attacks of these worms, and the diseased plants or the soil in which they grew is often dumped into the dirt-bin, and thus the trouble is propagated. In the southern states these nematodes are serious enemies to plants in the field and even to trees, but in the north they are confined chiefly to indoor plants. This indicates that the freezing of soil in houses which are attacked would be good treatment. When these worms attack Tomatoes the root is swollen into a shapeless mass which reminds one of the club-root of cabbage. The trouble is likely to be worse in plants which are carried over from one winter to another. In general appearance the injured plants resemble those attacked by the winter-blight except that the leaves are not spotted. The best treatment for this disease is to remove plants and soil, wash the benches and boxes with lye, and begin over again. It would, however, be a great saving of time and expense if the soil could be treated between crops with some material which would destroy the worms. Lye, quicklime and bisulphate of carbon have been tried unsuccessfully, but in boxes of earth which were salted and frozen no worms could be found.

Notes.

In consequence of the growing difficulty of procuring wood suitable for the manufacture of matches, German factories are now making them of compressed peat, which is said to be an excellent substitute.

According to a foreign journal, almonds are now counterfeited as coffee-beans are imitated. The artificial almond is made of glucose; color and form are copied to perfection, and the desired perfume is given by an application of nitro-benzine.

Anjou, in the Department of the Maine and Loire, in France, is a headquarters for the cultivation of medicinal plants. The ground is a slaty schist, and such plants as Belladonna, Camomile, Stramonium and Hyssop flourish well in it, and are grown on a great scale, and, according to an account recently given in *Le Jardin*, of Argenteuil, with large profits to their cultivators.

The first large exhibition ever held in Bulgaria was recently opened at Phillipopolis on a site known as the "Garden of Roses," which was formerly a Turkish cemetery, and is described as being beautifully disposed with avenues of fine trees, sheets of water and ornamental flower-beds. The most interesting feature of the show is said to be the Government exhibit of forest and garden products.

It has often been told that the Horticultural Hall on the World's Fair grounds at Chicago will be the largest building ever devoted to a purpose of this kind. But perhaps a new idea of its size will be gained from the statement that it will contain as much space as the combined areas of the horticultural halls which served at the Centennial, at the New Orleans Exhibition, and at the Paris one of 1889.

Particularly stringent laws exist in Switzerland for the protection of fruit-trees from animal and vegetable parasites. No man is allowed to treat his trees as he chooses, but a strict watch is kept over amateur as well as professional horticulturists. Even the Mistletoe, which frequently grows on Appletrees in this country, is regarded as a possible pest, and proprietors are obliged by the local authorities to free their trees from it at stated intervals.

An article in a recent number of *Gartenflora*, describing the alterations and embellishments recently effected in the famous gardens of Sans Souci, near Potsdam, says: "The view from the great fountain up the terraces to the palace of Sans Souci was being gradually shut off by the growth of the great American Arbor-vitæ (*Thuja occidentalis*). Therefore the trees have now been reduced to a height of about four and a half metres, and the uppermost twigs which remained have been skillfully gathered together with wires so as to form new tips. The observer notices no sign of this treatment, for the effect is entirely natural."

According to the Board of Trade reports, barks and bark-products to the value of £1,965,835 were imported into England in the year 1888. Of this amount a larger proportion represented cork-bark than any other kind, chincona-bark coming next, then extracts for tanning and dyeing, then tan-bark, and lastly cinnamon to the value of £44,061. The oak-bark produced in England itself during the same year was valued at £1,200,000, and the larch-bark at £200,000. The total amount of extent of the trade done in barks would, moreover, be perceptibly increased had numerous less important kinds, imported in small quantities, been included in the estimate.

A correspondent of *The Tribune* writes to complain that the English language has no word to describe the parcel of land on which the ordinary suburban residence is built. He dislikes the word "yard" for the strip of ground in front and on either side of such a house as utterly inadequate, and yet the word "lawn" is often inappropriate, for the place may not be a lawn. It would be absurd to call a fifty-foot lot by such a high-sounding name as "grounds." The word "lot" will hardly answer, as it is even more absurd to invite one's family to sit in the lot than to sit in the yard; especially is this so when there are two or three lots in the enclosure, if indeed there is any enclosure at all.

In many small Mexican towns primitive methods still exist in relation to the land; the town stands in the centre of a square league, which is held in common, and a certain space for cultivation is assigned to each householder. In the *American Architect and Building News* Mr. Sylvester Baxter writes that the orchards near one of these towns were separated from the intersecting lanes by high walls, and in each was usually a little house with a steep roof of thatch. The granadilla, the luscious fruit of a species of the Passion-vine, grew here in abundance. The fruit has a rich yellow shell, the shape and size of an egg; inside is a delicate pulp with seeds, something like the pulp of a gooseberry.

A Belgian horticultural journal notes as one of the most interesting and beautiful of recent novelties a new variety of the sweet-scented Centaurea (*C. suaveolens*), which is called by its introducers, Messrs. Dammann & Co., Centaurea Margaritæ. *C. suaveolens* has citron-yellow flowers, and a variety exists with larger light purple flowers. But the new variety is described as much more valuable, for its flowers are remarkably large, pure white, and most delightfully perfumed. "As to its culture," says our authority, referring to Belgian conditions, "the seed may be sown in April under glass, or in May out-of-doors. They do well in any kind of garden-soil which is not too strong or clayey, and they may be treated as annuals or biennials."

We have occasionally spoken of *Benthamia Japonica*, a shrub or small tree which was introduced some years ago to American gardens through the Parsons' nursery at Flushing. The flowers resemble those of our flowering Dogwood, to which it is related, although its white satiny bracts are more sharply pointed and somewhat narrower. It differs from our Dogwood in one particular, and that is, it flowers much later, and after the thick glossy leaves have attained their full size. Mr. Parsons has just sent us a few sprays of this plant, which is now in fruit. These fruits are borne on stems which are about two inches long, and they very much resemble a medium-sized strawberry in color and shape, and add much to the ornamental value of the tree. In *Benthamia fragifera*, a nearly allied Indian species, the berries, although they ripen in October, frequently remain on the tree throughout the winter. It is not likely that the fruit of the plant in question is so persistent. The flesh is soft and sweet, and will no doubt be a delicate morsel for the birds.

In a recent letter to *The World*, of this city, Mrs. Van Rensselaer writes that in one part of the South Park, Chicago, there is a long sloping bank of grass whereon the designer of pattern-beds has been allowed to do his worst. Here, for example, is a calendar with year, month and day wrought in gaudy colors and of great size, and every day the gardener makes such changes as will keep him abreast of the sun's revolutions. There is an arm-chair of House-leeks, colossal in size, which stands upright on the ground as a true chair would stand, and similarly constructed are two row-boats, each with its House-leek oarsman of life-size. There is a portrayal of the "Gates Ajar" and a literal piece of carpet-bedding, a roll of gaudily patterned carpet done in flowers, resting on the top of the bank and unrolling several yards of its length adown the slope. Of course, these sights are prepared for the supposed delectation of the public. But no one appeared to admire them, and a few stopped to jeer at them, while crowds constantly surrounded the little ponds in Lincoln Park, where some Water-lilies, Lotus and other beautiful aquatic plants were growing in natural disarray.

Several of the state experiment stations are making efforts to organize an intelligent warfare against weeds by publishing illustrations of the most noxious kinds, together with descriptions of their habits. This effort will be helped by the collection of weeds which Dr. Halsted is making for the Chicago Fair, and undoubtedly state agricultural fairs will follow the example and display collections of the weeds which are locally injurious. It has long been urged that instruction in this matter should begin in the public schools, where the gathering of collections of weeds by the children could be made both a pastime and an instruction. In Germany, wall-maps are hung in the schools with colored pictures of the most pestilent species at all stages of their growth, and the way in which their seed is distributed. One danger of such a practice would be that the child would be bewildered by the great number of species. The best plan would be to take up, to begin with, only a score or so of the worst weeds of any section and study them until they become so familiar that they can be identified at any season. Their character and habits should then be mastered, for treatment which might exterminate a perennial would leave the ground full of the seeds of an annual in the best condition to germinate next spring. When the child learns how the plant is reproduced—whether from seeds, roots, bulbs—when the seed ripens, how it is scattered, and acquires other information as to the plant's history and habits, he will be prepared to attack it in its most vulnerable point, and he will get a practical knowledge of a good many valuable truths in the science of botany at the same time.

Catalogues Received.

H. S. ANDERSON, Cayuga Lake Nurseries, Union Springs, Cayuga Co., N. Y.; Wholesale Trade List of Fruit-trees and Small Fruits; Root Grafts; New and Hardy Grapes; Ornamental Vines, Shrubs and Trees; Roses.—P. J. BERCKMANS, Fruitland Nurseries, Augusta, Ga.; Fruit and Evergreen Trees; Roses.—R. DOUGLAS & SONS, Waukegan Nurseries, Waukegan, Ill.; Wholesale Catalogue of Hardy, Ornamental and Evergreen Trees; Forest and Ornamental Tree Seedlings; Tree Seeds.—WM. ELLIOTT & SONS, 54 & 56 Dey Street, New York; Bulbous Roots and Seeds for Fall Planting; Pot-grown and Layer Strawberry Plants.—H. M. ENGLE & SON, Marietta, Pa.; The Paragon Chestnut.—JOHN R. & A. MURDOCH, Pittsburgh, Pa.; Fruit and Ornamental Trees; Flowering and Ornamental Shrubs and Vines; Bulbs.—A. J. ROOT, Medina, O.; Boxes for Farm Produce.—SCHLEGEL & FOTTLER, 26 So. Market Street, Boston, Mass.; Bulbs for Fall Planting.—G. L. TABER, Glen St. Mary Nurseries, Glen St. Mary, Fla.; Fruit, Shade and Ornamental Trees.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, OCTOBER 5, 1892.

The Islay.

ONE of the natural divisions into which botanists divide the great genus *Prunus* is distinguished by the ever-green foliage of the species referred to it, which, unlike other plants of the genus, produce their flowers in racemes developed from the axils of the leaves of the previous year, and yield fruit with very thin flesh and large thin-walled smooth rugose or reticulate-veined stones. To this group is given the name *Laurocerasus*, an ante-Linnæan name of the typical plant of the section, and its Linnæan specific name. *Laurocerasus* is a tropical and sub-tropical group, and is more widely scattered over the surface of the earth than any other of the natural divisions of the genus. It is largely represented in the Indian Archipelago and in South America; it occurs in southern China and Japan, in India, in the West Indies and Mexico, while in the United States three species are found. Of these one, an inhabitant of Brazil and the West Indies, finds its northern home on the shores of Bay Biscayne in Florida; the second is distributed through the maritime regions of the southern states, and the third is Californian.

To gardeners, the most familiar plant of the group is the so-called English Laurel, *Prunus Laurocerasus*, the type of the section and a native of the Orient, whence it was brought two centuries ago into European gardens, which it has done, perhaps, as much to decorate as any other plant. As a garden-plant the narrow-leaved Portugal Laurel, *Prunus Lusitanica*, a native of south-western Europe and the north African islands, among broad-leaved evergreens, is only second in popularity to the English Laurel in the parks and gardens of temperate Europe. Unfortunately these handsome plants are not hardy in the northern United States. In our southern gardens they are replaced by the so-called Mock Orange, the indigenous *Prunus Caroliniana*, a tree which sometimes grows to the height

of thirty or forty feet, and produces lanceolate acute lustrous leaves, short erect racemes of white flowers with conspicuous orange-colored stamens, and oblong black fruit half an inch in length. This tree may be found in the immediate neighborhood of the coast, growing in deep, humid bottom-lands from the valley of the Cape Fear River in North Carolina, to that of the Guadaloupe River in Texas. In the south Atlantic and east Gulf states it is not particularly common, but it abounds in eastern Texas, where it grows to its largest size, and sometimes forms impenetrable thickets in the neighborhood of streams. The leaves and young branches of this tree, like those of many of the species of *Laurocerasus*, contain at the period of active vegetation considerable quantities of hydrocyanic acid, making them dangerous to animals browsing upon them. The partially withered foliage is particularly dangerous, and a city ordinance of Mobile prohibits people from throwing into the streets the clippings of hedges of the Mock Orange. This Cherry-tree appears to have been one of the first native plants used by the settlers on the southern coast to decorate their homes, and now there are few southern gardens that are not beautified by a hedge or by a group of *Prunus Caroliniana*.

In California, *Laurocerasus* is represented by *Prunus ilicifolia*, the Islay, or, as it is sometimes called, the Spanish Wild Cherry and the Mountain Evergreen Cherry. It is a small tree twenty or thirty feet high, with a short stout trunk sometimes two feet in diameter, although generally much smaller, covered with thick dark red-brown bark. The branches are stout and spreading, and form a handsome, rather compact head. More often the Islay is a shrub rather than a tree, and sometimes, when it grows on the dry gravelly slopes of the southern coast-ranges, its stunted stems only rise a few inches above the surface of the parched soil. The leaves are beautiful, large, dark green and very lustrous on the upper surface, and usually sharp-toothed like the leaves of the Holly—a peculiarity to which this tree owes its specific name. The flowers in slender racemes, sometimes three inches long, are conspicuous from the bright orange-brown color of the large cup-shaped calyx, the small petals being pure white. The Islay flowers profusely, and the contrast between the color of the flowers and that of the foliage is strikingly beautiful. The fruit, too, is ornamental; it is sub-globose, sometimes two-thirds of an inch in diameter, and dark red when first fully grown, becoming dark purple or nearly black at maturity.

The Islay is a native of the coast-region, from the shores of the Bay of San Francisco to Lower California, extending inland in southern California to the western foot-hills of the San Bernardino Mountains, and preferring the neighborhood of streams, where, in moist sandy soil, it attains its best dimensions. It grows, too, on Santa Cruz and Santa Rosa Islands, off the California coast, where a form peculiar for its usually entire leaves has recently been discovered.

It was David Douglas, the hardy and intrepid Scotch botanist, the discoverer of some of the noblest trees of western America, who found the Islay sixty-odd years ago growing in the neighborhood of Monterey, although it was not properly described until some years later. Long before the days of Douglas, however, the Catholic Fathers, who penetrated California from Mexico and were the first white men to obtain foothold in that region, appreciated the beauty of the Islay and planted it in their gardens. They were wise in their generation, for, with the exception, perhaps, of the Great Magnolia, the *Tolou* (*Heteromeles arbutifolia*), another California tree, the *Umbellularia*, the *Madroña* and some of the *Rhododendrons*, North America does not possess a more beautiful evergreen tree. But the successors of the Spanish missionaries are less appreciative of the value and beauty of the flora of the Pacific coast, and, neglecting the plants nature has prepared for them, hunt through the antipodes for material which as often disfigures as beautifies their homes.

The Islay is an easy plant to cultivate; it grows with such rapidity that we are told of seedlings in the nursery of the Leland Stanford, Jr., University only three years old eighteen feet in height with heads fifteen feet in diameter. No plant is better suited to form an impenetrable hedge or to decorate a garden, and when California has passed through the stage which every new country experiences in gardening, of believing that exotic plants are better than the native products of the soil, the Islay will become one of the best ornaments of California gardens. Unfortunately, it is not hardy in the eastern states or in northern and central Europe, although on the shores of the Mediterranean it is apparently as much at home as on those of the Bay of Monterey.

The illustration on page 475, representing a wild specimen, is made from a photograph which has been obligingly sent to us by Mr. E. L. Woods, of San Francisco.

THE danger that the Central Park will be overcrowded with statues and other monuments increases from year to year; and, despite the fact that greater care is now taken than was taken even a few years ago to exclude those of an inartistic kind, public sentiment is still not sensitive enough on this point; and as long as public sentiment does not sustain them, the difficulties with which the Park Commissioners have to contend in deciding with regard to suggested monuments must be very great.

No statue ought to be admitted to a public park unless it satisfies the taste of competent judges, for poor works of this kind do injury alike to the memory of those whom they profess to honor, to the reputation of those who bestow them, to the best interests of the public, and to the beauty of the great pleasure-ground itself. Still more. The mere fact that a statue is intrinsically good does not always justify its admission to the Park; it must be not only good, but good as an ornament for a park. And, moreover, it must be appropriate to the special site selected for it; or, to turn this fact the other way, an appropriate site for it must be selected. There are certain situations in a park where no statue or monument would look well, and there are others where a work of one kind would look admirably well, while a work of another kind would injure the effect of its surroundings while not appearing to good advantage itself.

The more formally arranged portions of a park are, of course, those where works of sculpture or of architecture, or of the two combined, are most appropriately placed. We are glad, therefore, to learn that the Park Board, while recently accepting the suggestion of Mr. Calvert Vaux, their landscape-architect, that a proposed Thorwaldsen statue be placed near the park entrance at Sixth Avenue and Fifty-ninth Street, at the same time approved his general recommendation that the Fifty-ninth Street frontage of the Park be borne in mind as the station for monuments which may be offered in the future. Here, between the trees which border the sidewalk in a symmetrical line, such objects can certainly be placed to better advantage than in any of the naturally treated portions of the Park. And, if such a change is feasible, we should be glad to see carried out the further suggestion that some of the statues already standing in the Park be removed to the sidewalks around its borders.

As the Mall is a formally arranged feature of the Park, it likewise offers an excellent station for statues. If a fine row of monuments existed here, alternating with the regularly spaced trunks of the overshadowing Elms, and having their pedestals partially draped in close-growing vines, as is the custom with park monuments in Paris, the effect of this long perspective would be beautiful indeed. But, unfortunately, the few monuments which have already been placed here are poor ones; to increase their number without bettering the quality would be most unfortunate; and, therefore, these sites should be preserved with especial care by the Park Commissioners, and be jealously re-

served until, from time to time, works of an exceptionally high degree of artistic merit and appropriateness may be offered to the city.

Overland in the Cayuga Country.—IV.

WITHIN two or three miles of Geneva begins the fruit region of western New York, which stretches away to Lake Ontario and Niagara Falls on the north-west, and to Chautauqua County on the south-west. All this country is not devoted to fruit-growing, but orcharding is its dominant industry, except in some extensive grain sections like the famous and superb Genesee valley. The fruit-interest is comparatively new here, although the Apple-orchards of western New York have been famous for many years. The oldest vineyards are twenty or thirty years old, but most of the Grape-interest is comparatively recent. All fruit-growing in this part of New York is flourishing, and is rapidly extending. This is especially true of grapes, plums, and, to a smaller extent, apricots. The small fruits are yearly gaining in importance, as is shown by the reports from the numerous canning factories and evaporating establishments. Besides this, the nursery-interest is the largest and most varied on the continent. All about Geneva and many other cities and villages of western New York are nursery blocks, ranging from a few square rods of Quinces or Plums or Berries in some village yard to a hundred acres cultivated by the nurseries. The little patches here and there afford a profitable use of bits of land, for the product, if carefully grown, is sure of sale to the nurseries. Much of this stock is grown upon contract for the nurserymen, who often furnish the buds, and sometimes the seed. Much of the nursery stock sold through Rochester firms is grown at Geneva. Many of the fruitmen are graduates from the nursery business, and their training has made them, as a class, the most acute fruit-growers whom I have ever known.

T. C. Maxwell & Bros. have several farms in fruit and nursery stock, and their places may be considered types of the extensive fruit-culture of this region. At this place they have 150 acres of fruit in bearing. We drove through a continuous orchard of Plums of eighty-five acres, every tree heavy with the promise of a bountiful crop. The orchard is scrupulously clean, for all the Geneva growers believe in clean and frequent culture. The tops are started four or five feet high. There are some two dozen varieties in these orchards, of which the most profitable are Reine Claude, Purple Egg, Fields (often called Early Bradshaw) and Bradshaw. Other prominent varieties are Purple Damson, Frogmore Damson, French Damson, Farley, King, Guis, Coe's Golden Drop, Copper, German Prune, Smith Prune or Diamond, Middleburgh, and Monarch, the last a very valuable, large, blue, late plum. Here are also eighteen acres of Quinces, of Orange and Rea, the former being the better. Upon another farm across the lake the Maxwells have a block of Quinces of thirty acres, and the orchard is famous among fruitmen. Here are ten acres of sour Cherries, English Morello and Montmorenci. The Montmorenci is a famous cherry in this region, coming in a little ahead of the Morello. This is the Montmorenci ordinaire; another variety, the Montmorenci Large-fruited, is an unreliable cropper, and is rarely grown in western New York. The remaining orchards contain Apples, largely Baldwins, and other common varieties.

All these orchards, of one hundred and fifty acres, are carefully sprayed for insects and fungi. A hand field force pump carried upon a tank in a wagon and Peerless nozzles are used exclusively. Plums are sprayed two or three times for the septoria or shot-hole fungus, which causes the premature falling of the foliage, but for curculio the sheets are still used. Plums are treated with the ammoniacal carbonate of copper. The knot is fought industriously. Twice during the summer every tree is carefully examined by two men, who walk upon either side of the row. This examination, together with the search which is made in winter, has thus far kept the knot in check; but all the growers in this region are apprehensive of this disease, and the new law for its extermination is being enforced with vigor. Cherries are also sprayed with the copper carbonate to combat the leaf-blight, a disease which causes the leaves to fall before the fruit matures. The best fruit-raisers recognize the fact that abundant and healthy foliage is essential to a good crop of fruit. Quinces and Apples are sprayed twice with Bordeaux mixture, about a week after the blossoms fall, and again two weeks later. This treatment is aimed at the leaf-blight on the Quince and the scab-fungus on the Apple. For both Quinces and Apples, Paris-green is mixed with the fungicide for the purpose of killing the Codlin-moth

larvæ. This is a fair sample of the attitude of our New York fruit-growers toward spraying. The practice has taken an assured place among the operations of the orchard, and I imagine that if either spraying or cultivation had to be given up for any year, most growers would discontinue the cultivation.

The Maxwells, in all their orchards, devote the land exclusively to the trees, and this is the common method; but an entirely different system may be seen upon the farms of S. D. Willard, whose methods, like the man himself, are unique. Mr. Willard has long been known as one of the most reliable and energetic of the New York nurserymen, but his legitimate fruit interests are very large and receive the greater part of his devotion. Although Mr. Willard's chief energy is devoted to Plums, concerning which he has the most exact knowledge, he grows every fruit which will succeed in New York. He is particularly fond of the English Gooseberries, Currants and Apricots. He derives intense pleasure from every tree and variety upon his plantations, but the ultimate test of every new thing is its commercial value, and I have never yet found an establishment which so happily combines the two sides of fruit-growing—the pleasure and the profit. The greatest energy is directed in securing new varieties, both domestic and foreign, and these are top-budded or top-grafted into old trees, being designated by numbered tags. Several valuable fruits have been brought to notice by Mr. Willard in this manner, prominent among which are some of the Japanese Plums, especially the Burbank, which have here been well tested for our northern country. Mr. Willard's method of fruit-growing is peculiar and may be described as a mixed intensive method. The leading fruit of the plantation is systematically planted, but the spaces between the trees are jammed full of the most puzzling assortment of fruits and other plants. His oldest fruit-plantation was originally an Apple-orchard. Between the Apples were set Plums, and as these and the smaller fruits become more profitable, with approaching maturity, the Apples are cut off. "Apples are too slow for me, and there is not enough in them," is Mr. Willard's characteristic remark. "They are profitable for larger farms and cheaper lands, but I can make more money from the more perishable fruits." So the skeleton of this unique fruit-plantation has been gradually transformed from Apples into Plums. Between the Plums in some places are Quinces and Berries, or perhaps Grapes, here and there; now a row or a few trees of Pears, mostly of the favorite Kieffer, a plantation of Blackberries with Strawberries between; a bit of English Gooseberries or Raspberries or Currants, or a few rows of nursery stock, very likely mound-layered Multiflora Roses or Magnolia Stock. Everything is crammed, jammed and tucked up, and everything is remarkably thrifty and productive. In fact, one is astonished to find such a system successful, and with most men it could not be so, but here it works to perfection. It is the only place in which I was ever really satisfied that such thick and mixed planting is successful. The secrets of success here are manure and cultivation. The land is naturally strong, and would generally be regarded as rich enough for fruit-growing, without fertilizing; but the soil turned up by the cultivator along the rows shows a liberal quantity of fine stable manure well mixed in. Pruning, spraying, bug-catching, and all the other requisites to the best orcharding, proceed upon well-considered plans. There are several of these places where Mr. Willard practices this intensive culture, or something like it, and everywhere one is struck with the enthusiasm and determination of the man. There are nurseries of large dimensions belonging to him and scattered over a wide territory. The feature of these nurseries which especially strikes the visitor, is the enormous quantity of Birches, for here, I suppose, the ornamental Birches are grown in greater quantity than at any other establishment in this country.

But a volume could easily be written upon the horticulture of Geneva. It is altogether a remarkable and productive country, and the soil and the inhabitants appear to be as fresh as they were in the days when the great wheat-fields covered these hills and plains. Here, too, is the State Experiment Station, with unrivaled facilities, in its own equipment and in the neighboring farms, for horticultural work. But we have already tarried long at Geneva, and we must turn homeward. We again round the foot of Seneca Lake, but instead of striking diagonally across the divide toward Cayuga, we skirt its shores upon the west for many miles. Here we miss the villages which we found in the outward journey, but, what is more to our liking, we are constantly coming upon orchards and vineyards and snug homes. Yet this western shore of Seneca is only partially developed horticulturally. It has great possibilities which are coming now to be appreciated. There

are isolated plantations of great extent, the most notable of which is the great Smith farm near Ovid, overlooking the lake from a most commanding bluff. In some respects this is one of the most important orchard and vineyard establishments in the lake region, particularly for the great number of apricots which are growing in orchards like plums or peaches and which are found to be a successful fruit for market. This great plantation stands like an island in a desert of indifferent old-style farms, a perennial proof of the possibilities of the soil when tilled with diligence and fertilized with thought.

Soon we turn eastward over the hills. As we rise above the lake we pass away from the orchards and vineyards and find ourselves among broad fields of hay and grain. There is little corn, and the higher we go the less corn we see. Now Seneca Lake lies far below us like a broad blue ribbon, and the patchwork hills to the westward are tilted in haze against the sky. It is an inspiring panorama, and we stop our horse often that we may look back upon it. But the immediate prospect is no longer pleasing. We are reaching the tops of the hills and we are far from any village. The land looks cold and thin. It is no longer cultivated in warm, snug fields. It is nearly all in grass, and the land has long since lost its blood and body, as the plant-food it contained was taken up by the grass and sold away in the hay. The acres of daisies, the broken fences, the staring barn-yards, the half-finished or ruined farm-houses, all show that the farmer has been made to pay the penalty of his own ignorance and indifference. He is too far from town to attend the institutes and to receive the benefits of contact with his fellow-men, and somehow he has never noticed that the farms beyond him upon either slope, where grain and corn and grass have been rotated these many years, are much better and brighter than his. He is too high up to grow corn for market, but he can do something beside raise grass, or he can sell his grass as beef or mutton or butter and have the manure for his land. But he has sold the heart of his farm to the hay-dealer years ago, and he is an object of pity now. Cold and bare and cheerless he drags out the weary years upon these Cayuga hills.

Now we pitch to the eastward into warm, fertile valleys and by cosy homes, and under their inspiration we jog on happily to Ithaca and end a pleasant four days' ride.

Cornell University.

L. H. Bailey.

Shongum.—II.

THE great thickness of the sandstone ledges of these mountains, and the natural cementing of the crevices in these reservoirs by disintegration, have preserved several small lakes amid the uplands in positions that add much to the beauty of the scenery and to the variety of the vegetation. Lake Minnewaska is nearly a triangle in shape, three-quarters of a mile long by a fifth of a mile wide, and forty feet deep in its deepest places, while the shores are everywhere bold and rocky. Its clear pure waters reflect the tint of rock and foliage, or, like a mirror, lie open to the sunshine and the sky. Along one side the walls of white stone are regular in their stratification and rise perpendicular to the height of ninety feet, with a buttress here and there supporting an overhanging slab, square cut, as if made with tools. All this is covered with leathery brown lichen, indicating great age, and testifying to the hardness of the material on which it grows. Huge heaps of rock along the margin of the lake, and running up into the few ravines that break the wall, give place for the growth of trees and shrubs. There are Pines ten inches in diameter and thirty feet high, with no apparent diet except sandstone and water; but the curious and far-reaching wisdom with which roots sometimes larger than the trunk of the tree are twisted among the stones and wedged into their crevices suggests the possession of some hidden knowledge of food by the *Pinus resinosa*. Under these, and among the debris they have made, the *Kalmia* and the pretty Mountain Holly (*Nemopanthes fascicularis*) luxuriate, clothing the feet of the giant cliff with a soft green mantle as they dip under the water.

Opposite the cliff the shore is more irregular in outline and slightly receding, so as to give place among its ledges for the most picturesque growth of trees, among which the Peperidge (*Nyssa*) is frequent, and already gay in its brilliant autumn colors. Along this edge of the lake, also, among more common Ferns, is the delicate *Osmunda regalis*. The eastern end of the lake is narrow, and here the walls break down to give an enchanting perspective, with the blue hills along the Hudson on the horizon. A similar break at one of the western corners gives a glimpse of the Catskills and the nearer mountains, which we watch with eagerness when the glory of the sunset makes a sublime picture of earth and sky.

Lake Mohonk lies to the north-east, seven miles away, and is smaller and more regular in outline. Lake Awasting, five miles to the south-west, holds about the same level with its fellows, of 1,650 feet above the tide, and is much larger and deeper. Its length is two miles, its greatest width half a mile, its greatest depth eighty feet, with the same bold, rocky shores and general formation of cliff and forest. But from this lake, and from an extensive marsh not far below its outlet, flows the large stream which, in its descent, makes the poetry of these woodland walks, and for many miles gives the voice of its music, in numberless cascades, or in its two roaring falls, to swell the grand diapason of the winds in the Pines that crown the cliffs above. The stream is a constant joy and excitement, and reconciles the dwellers here even to that horror of invalids and idle people, a rainy day.

After a rainy day I went to Awasting Fall, through a woodland path that descends sharply from Lake Minniwaska three-quarters of a mile to meet the stream. The growth just here is chiefly of Chestnut and Maple, both Red and Sugar Maple, mingled with Birch. There are no large trees, but the graceful creatures stand like young matrons with their children of different ages around them and their babies at their feet. The Sassafras is everywhere. I have great sympathy with this tree because of its love of variety. I am persuaded it would like to be a Dolly Varden, and flaunt in gay clothing, but, being devoid of all expression of such taste, it can only blush a dull red at the tips of the wet fingers it puts forth to greet us, and show a little dash of color in its petioles; and so it constantly employs itself in changing its form of garniture. No matter how small or how large it may be, did anybody ever see a branch of Sassafras where the leaves were all alike?

Interspersed among these were a few Chestnut Oaks, growing low and bushy, and higher than all rose the scattered Pine-trees. The path descending over ledges of white rock, where grow scant mosses and lichens, and along the edge of a cliff, which walls in the head of a deep valley, brought us to a point where the stream, already vexed to foam in its swift course, makes a leap of seventy-five feet to the pool below. On the further side the rocks rise to a perpendicular height of one hundred and fifty feet, and then recede, still rising, broken and covered with Pines, to a greater height. Beneath flows the stream, while on the nearer side the cliffs are curved around a deep basin that may once have been a lake. The debris of fallen rock and tree, rising gradually from the stream half-way up this cliff, makes a deep soil always moist and warm and sheltered. Here once grew great Hemlocks and Pines, but they became food for the mill below, and since then fires have often swept over these heights. Now as I stood beside the stream at this lower level I found a twilight made by tall Maples and Chestnuts, with a White Oak here and there, and abundance of Black Cherry, which might in time become valuable, and many Birches, among them *Betula papyrifera*, which I did not find on the hill above. There were thickets of Laurel now ripening its spiked berries, the Rhododendron was vigorous and tall in the black soil, and occasionally a Rhodora grew beside the path.

Reluctantly I turned from the beauty of the waterfall. When I had seen it before it was a filmy veil, falling over a projecting edge curved like a scimitar, and breaking into spray through which the morning sunshine wove prismatic colors, and a thousand broken rainbows danced over the worn gray rocks behind the waters. Now the air trembled with the roar of the mad stream, and the gorge near it was full of mist like rain, while the tormented pool dashed itself far over its usual bounds. Near it, against the cliff, huge rocks are piled, and these, green with thick mosses, nourish the Polypodium and other Ferns, while tall brakes grow between. Half-way down the cliff and wholly under its shelving edge, a Black Birch had rooted itself in the debris, and, growing luxuriantly, held in its upper branches a bird's nest, empty now and with the spray drifting over it. The ground was soft with mosses and covered with the Partridge-berry vine, the Swamp Blueberry and the Wintergreen.

In open places where the path touched the stream we saw it bathing the roots of Alder and Elder bushes, while Black-berry and Raspberry bushes caught us in passing, with an offering of fruit. In the clefts of the precipice opposite, small Pines and Hemlocks had taken root, and tiny Laurels, their leaves already ripe and red, and tufts of Columbine and Golden-rod; while the Hardhack, *Spirea tomentosa*, with its relative *S. aruncus*, grew plentifully by the margin, and nodded their white and crimson heads to each other across the amber flood speeding by with flecks of white foam.

Thus far for more than half a mile we followed our rapid

guide, until the path merged into a wood road. *Azalea viscosa* bordered our way. All along, as we had looked up through the confused stems of the thickly growing trees, we had seen evidence of former greatness in prostrate massive trunks that now only serve as food for their successors. But beautiful in decay they were, covered with moss and Lycopodium, and the dwarf Club Mosses and wonderful Lichens, often in brilliant tints of orange and curious coralline forms of fungus, red, yellow and creamy white, as if they had mistaken the depth of this basin for the bottom of the sea.

And then our steps led to the country road, and crossing it we came in a few minutes to the "high Peterskill." This outlet of our stream is at a point where one wall of the mountain runs past the other, and the current makes a sharp turn, after taking its first leap into the gorge, over the foundations of that which had hitherto restrained its course; then, gathering itself, springs across the ledges two hundred and fifty feet down the ravine; and though beyond this point it is only a succession of cascades, after a rain it becomes a cataract, with no apparent division in the raging, plunging mass that flings its foam high in the air as it descends with a volume of sound multiplied by echoes from its rocky borders.

For these still rise high above it—on the west perhaps a thousand feet from the bottom of the ravine, which is only about seventy-five feet wide. But everywhere the graceful Birch and Poplar, the Chestnut and Oak, the Maple and Sassafras, and the Pepperidge crowd among the Pines that have wedged themselves in the crevices of the rock, and the Mountain Holly, with its brilliant berries, and the Dogwood, with crimsoning leaves, in its gray escarpment of rock and the music of its rejoicing waters, a thing of beauty worth going far to see.

The remains of a substantial mill, half-way down the gorge, and near the road, tell that this wild creature was once made the servant of man's need for lumber. A still greater wrong was done by robbing it of the historic Indian name, Aioskawasting, and calling it the Peterskill. But under this latter cognomen it is known on the lower slopes of the mountain, where it pursues its course to the north-west until it joins the Roundout River.

When this region was covered with the heavy forest that sheltered the sources of springs now bare and dry, the stream had many affluents, and must have filled its whole channel, as the water-worn rocks everywhere testify. Even now, after long, heavy rains, or when snow melts in the spring, its volume is so much increased that bridges five feet above its usual level are carried away. Then the Awasting and the Peterskill falls are said to be magnificent and almost fearful in their might. After the lumbermen had sacrificed the primeval forest the land was left to recover itself, but the beneficent processes of nature have been constantly interrupted by fires that have raged everywhere, often burning deep into the soil and destroying all hope for the future. Now, except in deep basins such as I have described, the soil is poor and thin, and the green robe that covers it is more for beauty than for use. Yet even this the greed of man constantly imperils. The small farmers on the lower slopes, and the squatters hidden among the rocks, make a poor living by the harvest of Blueberries and other kindred fruit, and often have set fires to burn over large tracts because a growth of this kind follows. Those who would prevent this spoliation are obliged to use constant watchfulness, and all kinds of moral and material suasion, for the law gives them no adequate redress. The progress of civilization is shown in nothing more than in making man care for the welfare of all, above his individual good, and though the idea obtains slowly, there still are evidences that it is taking root in this neighborhood.

Minnewaska.

M. H. P.

New or Little-known Plants.

Aster sericeus.

THIS handsome little species should be in every good garden of hardy plants. The stems, which are paniculately branched above, are only a foot or two high, and are well clothed with oblong leaves, which are silky white from the soft pubescence with which they are entirely clothed. The color of the leaves and of the bracts of the floral involucre serve as an excellent background for the ray-flowers, which are large and a deep violet color, and in late autumn make this plant exceptionally beautiful and interesting.

Aster sericeus is a native of dry uplands and prairies from Minnesota and Illinois to Tennessee and Texas. In cultivation it is perfectly hardy on the Atlantic seaboard, and quickly adapts itself to new conditions and surroundings. Our illustration below is from a drawing made by Mr. Faxon of a plant in Professor Sargent's garden in Brookline, Massachusetts.

Fig. 80.—*Aster sericeus*.—See page 472.

Foreign Correspondence.

The Chiswick Garden in England.

AN interesting garden in England is the experimental ground of the Royal Horticultural Society at Chiswick, a suburb of London, and within easy reach of the great metropolis. It comprises about eleven acres and is devoted to testing the merits of fruits, vegetables and flowers sent for trial by the leading nurserymen of Eng-

land, the Continent and America. Trials are conducted each year with the greatest possible care. At the proper season the committees visit the gardens and adjudicate upon the varieties. The potatoes, for example, are lifted in their presence, so that they can ascertain other points besides the appearance and table qualities. Before the Royal Horticultural Society expended such large sums in the acquirement of the gardens at South Kensington, laid out in costly style, but never profitable, the Chiswick Gardens were much larger, and in the preface to the fourth volume of the *Transactions of the Horticultural Society*, published April, 1822, we read that "a tract of land at Chiswick, which has been recently taken of his Grace the Duke of Devonshire, under a lease, renewable for ever, at the will of the Society, appears to afford in point of soil, situation and other conveniences, everything that could have been desired." The Chiswick fêtes held in the earlier days of the Society were more fashionable than even the fêtes of the Royal Botanic Society at Regent's Park at the present day. The grounds were the centre of attraction for the élite of London, and the fêtes were graced by the Royal presence. These palmy days are over, and a few years ago it seemed to be a matter for consideration whether the Chiswick Gardens should not be given up. A strong feeling for their retention prevailed, and Mr. A. F. Barron, the superintendent, is permitted to carry on the good work that he has accomplished over a long series of years.

It is a pleasure to record, after a recent visit to the gardens, that they are gay with flowers, and the plant-houses are in excellent condition. But they are only recovering from a period of depression, and in time, as the Society sees its way to extend more liberal help to the gardens, we shall find that the horticulturist will gain even more solid information than can be gleaned at the present day. It was at Chiswick that the great Apple Congress was held which did much to place the nomenclature of this fruit upon a proper footing, and the Pear Conference took place later, while during the past three or four years conferences on flowers, fruits, shrubs, and conifers in particular, have brought together horticulturists from many parts of England.

These events have been duly recorded by Mr. Watson in his interesting letters, and, therefore, nothing further need be written concerning them.

A few of the most interesting features in the grounds at the present time may be noted. In the central walk, leading from the great vinery to the private gate of the superintendent, the most striking effect in color is gained. On one side a collection of Dahlias is now at the height of its beauty, and on a cool, moist, shady border, skirting by the side of a hedge of Box, the Tufted Pansy, as these hybrid

Violets are called in England, is thoroughly at home. The beds are filled with either one distinct variety or just enough to secure contrast in color. A collection of Tufted Pansies from such growers as Messrs. Dobbie & Co., of Rothsay, Scotland, entirely fills some of the beds. These plants are one sheet of color, varying from pure white to the profound purple of the great market kind, Archie Grant, one of the best self-colored varieties in cultivation. The flowers are of superb depth, bold, and borne with great freedom. This, with Bluebell, a variety of a paler, brighter shade, are the chief Tufted Pansies used in the border parks, where they form edgings or a groundwork to taller plants.

A fine effect is gained by a single bed of the variety *Plenus maximus* of *Helianthus multiflorus*. It is the finest of the late-blooming Sunflowers, the stems rising five or six feet in height, the leafage abundant, and the bold yellow flowers of great depth and substance. The best method of planting is to permit it to stand alone, with nothing for contrast, although, of course, careful use must be made of such bold, not to say garish, plants. We often crowd too much yellow into our gardens in the autumn.

At Chiswick, Messrs. Cannell & Sons, of Swanley, who grow the Tuberous Begonia largely for bedding, have several varieties for trial, and the flowers, especially of the crimson kinds, are intensely brilliant. Messrs. Vilmorin & Cie., Paris, and Messrs. Sutton & Sons, of Reading, are represented by varieties of Begonia *semperflorens*. They are delightful bedders, dwarf, compact and smothered with bloom. The best of these is Vernon's variety (*rubrum*), which appears to be the same as the Crimson Gem of Messrs. Sutton & Sons. The plant is about nine inches or a foot in height, the leaves deep green, in which there is a suspicion of chocolate, and the flowers are rich crimson, making a fine contrast. A bed of it would be very effective, and so would an edging of it if it bordered a mass of plants which properly harmonized or contrasted with the distinct quality of its foliage and flowers. Princess Beatrice is a little gem; the leaves are small, and the flowers pink and white, so profusely borne as to hide the foliage. We have few more useful edging-plants, and, like the ordinary tuberous types, it succeeds well even in unfavorable summers. Afterglow is a good kind with crimson flowers. A variety of *B. erecta*, from Vilmorin, named Nain Rouge Foin, is remarkable for its compactness and splendid crimson flowers that glow like fire. A very interesting group from the same Parisian firm comprises a number of double varieties with small flowers, the centre like a little rosette set in broad segments. Their freedom in flowering is extraordinary.

Early this year a note appeared about Fuchsia Dunrobin Bedder in GARDEN AND FOREST. Its behavior this year justifies all that was said in its praise. It is a charming dwarf hybrid, very free, and two beds of it here are not the least interesting of the various arrangements.

One of the principal flowers this year at Chiswick is the herbaceous Phlox, and collections have come from such well-known growers as Messrs. Paul & Son, of Cheshunt; Monsieur Lemoine, of France, and Mr. Forbes, of Hawick. It is worth while to name a few of the best, these having an excellent habit, dwarf, compact and bushy, and bold spikes of finely formed flowers of decided colors. A small revolution is taking place in regard to the perennial Phlox. Little is now seen of the tall, ungainly, scraggy types once so common, and, although there is no merit in mere dwarfness, the flower does not suffer from being shorn of much of its height. The case is different with the *Antirrhinum*, and the present practice of dwarfing it deprives the plant of its natural gracefulness and charm. I will give the names of a few of the best varieties that now provide the gayest masses of color: Iris, mauve-purple, dwarf; Henri Murger, a bold large flower, white with crimson eye; Eugene Schott, pink, white centre, the plant but a few inches high; Monsieur Henri Jacotot, white, crimson cen-

tre; Faure, very dwarf and compact, the leaves of a deep green color, and the flower large, white, with pink eye; Le Naine Blanche, white, yellow eye; Eugene Dauganvilliers, pinkish; Boule de Feu, brilliant crimson, remarkably effective; Jeanne d'Arc, a very beautiful white variety, not growing more than about two and a half feet in height; La Ville de l'Air, white, crimson eye; Bayard, purple; Pluton, crimson; Croix de Sud, white, with purplish rose centre; Jenny Greive, splendid truss, the flowers white, with a purple-rose centre; Delicata, white, rose-purple eye; Eclairer, white, with centre of similar shade; William Robinson, salmon-rose; Hain Bébé, purple-rose, very dwarf; Neptune, almost white, the leaves very dark green; Masseuet, fine truss, rose, the centre deep crimson; Longchamps, white, purple-lilac centre; Paul Bert, lilac-purple, shaded with white; Pluto, crimson-purple, fine truss, the leafage very dark green; Avalanche, white and flambeau scarlet. Many of these have been given awards by the Royal Horticultural Society, and, as will be seen by the names, are mostly of French origin.

Beds of Tea Roses, the glorious Japanese Anemone in variety, very charming the white against the rose, and African Marigolds will interest the visitor. The French and African Marigolds are placed in a narrow border, skirting the fine old wall that divides the splendidly kept lawn facing the old council room from the plant-house. And when one sees this type of Marigold, after being allowed to develop its beautiful leafage and fine bold flowers, one is compelled to contrast its appearance here with its appearance on exhibition boards. Like the Aster, the Hollyhock and other things one could name, the blooms are often cut with a short stem and are stuck on the boards without a single leaf. Fortunately this barbarous practice is passing away. One of the most pleasing beds we have seen this season was composed of the variety Lemon Queen, the flowers of a soft shade of yellow and large, in the centre, with an outer ring of a deep orange color.

Zinnias give their share of color, and the yellow flowers of a bed of *Cassia corymbosa* show well against the abundant green leafage. The *Bouvardias Humboldti* and Alfred Neuner, planted out when all fear of frost is over, bloom profusely throughout the summer. The flowers of *Humboldti* are white, sweetly scented, and those of the other kind white and perfectly double, like a little rosette. *Hedychium Gardnerianum*, with its spikes of bright yellow and fragrant flowers and rich musa-like leaves, is an excellent summer plant and gives an attractive variety. The use of such garden-plants as we have mentioned is a grateful relief from the round of Pelargoniums and carpet-plants year after year, and furnish pleasant pictures from the time the spring bulbs are over until the Michaelmas Daisies have faded. The collection of Sunflowers, which is large and comprises the best kinds, ought not to be passed without notice.

The rockery is not one of the least important of the many fine rock-gardens that abound in England, and its interest will be increased by the handsome gift from the Royal Gardens, Kew, of two hundred plants of the rarer kinds. But it cannot, of course, compare with such picturesque rockeries as that of Kew, a veritable treasure-house of rare things, splendidly grown, or of the famous rock-garden of the Messrs. Backhouse at York. Space fails to make mention of the collection of Figs grown in the house once given up to Palms and foliage plants, and of the vinery, one of the most extensive in England. In spring Chiswick is a garden of blossoms from the numerous Apple and Pear trees, of which there is an extensive collection. Altogether, Chiswick, though small, surrounded by residences and shorn of much of its former glory, is a charming spot, beautiful for its flowers and of the greatest interest to the practical horticulturist from its careful trials of fruits and vegetables and garden-plants, the most common kinds of which are not neglected.

London.

V. C.

Cultural Department.

The Cultivation of Tuberous Begonias.

AT the Begonia Conference held at Chiswick on the 23d of August last the senior partner of the firm of John Laing & Sons read a paper, of which we have before spoken. The very interesting history of Tuberous Be-

notes on the more practical points of propagating and cultivating these plants, and we therefore give in a condensed form the last portion of his admirable paper, a copy of which has been kindly furnished us.

There are at least four ways of propagating Tuberous Begonias—by seeds, cuttings, leaf-cuttings and division of the tuber. The first two are the most practicable and profitable.

Fig. 81.—The Islay, *Prunus ilicifolia*—See page 466.

gonias from the time of the introduction of *Begonia Boliviana*, the list of the various species whose blood in turn has been added to the mingled strains to produce the present remarkable race; the care which has been exercised to improve the size, shape, texture and color of the flower and habit of the plant, have all been spoken of before. Our readers will be glad to hear some of Mr. Laing's

Increase by cuttings is essential only in the case of choice standard kinds which are to be kept true to name. These are used chiefly for pot-culture, and as the most improved or advanced types of the race from which the finest strain of seeds is derived. Young shoots from near the base of the plants make the best cuttings, and they may be inserted any time during the growing season, but the earlier the better they will root and the better tubers they will form. A few of the young

growths that arise from the tubers in spring may be taken; but the fact must not be overlooked that to take the same liberties with them as with Dahlias would be ruinous to a good display of bloom on the old plants for a season. The cuttings should be inserted singly against the side of thumb-pots in a compost consisting of loam, leaf-soil and sand, in about equal proportions, and plunged in cocoanut-fibre in the bed of a propagating pit or frame, and shaded till they have emitted roots, and may be grown on if required for late blooming. The young plants should be kept in the cutting-pots till the following spring, and this is the more essential in the case of late-struck cuttings, but, where practicable, the latter should be potted and kept growing.

Propagation by seeds is at once the most legitimate, speedy, profitable and certain mode of increasing this class of Begonias, either for pot-culture or summer bedding. There will always be a certain amount of speculation with regard to the color, habit and character of the seedlings the first year, but, if derived from a good strain, they seldom fail to give satisfaction, and may be assorted for future work as they come into bloom. They may be sown at almost any time of the year, according to the convenience and requirements of an establishment. For my purpose I find the third or fourth week in January is the most suitable. Those who have a sufficient command of fire heat will find it advantageous to sow early in the year, as the seedlings are less liable to damp off than when they are germinated in May, June or July.

The seeds are sown in square, round or oblong pans or shallow wooden boxes, in a compost of light porous material, consisting of flaky leaf-soil, a little loam and plenty of sharp sand. This is mixed, and used in a rough state, with some finely sifted material on the top to form a smooth and level seed-bed, which is pressed firm, watered, or more suitably dipped, and then the diminutive seeds carefully sown. The pans or boxes are placed in a temperature of sixty-five to seventy degrees, with more bottom-heat. The seedlings are pricked out into other boxes from time to time, as soon as they can be handled, with a finely pointed piece of wood divided at the point to lift the seedlings. As they germinate very unequally, and in succession, the work of pricking them off employs some men and boys for weeks together. When the seedlings begin to get crowded they are transplanted into other boxes at a greater distance apart. By the middle of May they are ready for hardening off. During the first three weeks of June a staff of men and boys were constantly employed in planting those now in the open ground. By this time a large proportion of them have commenced to bloom, and several thousand of the most promising doubles, some of them gems, are transferred to 48-size pots and placed in new houses specially built for their reception.

The ground in which the seedlings are planted out is heavily manured and roughly dug up to the action of frost in autumn. Old tubers intended for bedding out should be started about the last week in March or the beginning of April; small-sized pots will be quite sufficient for them. A warm and showery month of June, and rather drier weather in July and August, are most favorable to Begonias in the open ground.

For pot plants one-year-old tubers are the most generally useful; but those of two or three years' growth make the finest specimen plants. When four years old they degenerate, some sooner, some later; hence the necessity of raising young plants to keep up the standard of perfection. The first batch of plants may be started about the end of January or the beginning of February, and they will flower in April or May, according to the amount of sunshine they enjoy or the artificial heat used. Successional batches of tubers may be put into heat during March or April to flower in June or July, and be it observed, that the more slowly they are brought forward, the more sturdy and durable will they be. Put them singly in small pots proportionately to the size of the tubers, in a compost consisting of equal parts of fibrous loam, leaf-soil, and sand in a rough or lumpy condition. Press the soil rather firmly, if short growth and a long season are desired, merely covering the top of the tuber. Stand the pots on a bed of cocoanut-fibre or plunge them into it, and keep the temperature of the house at sixty-five to seventy degrees. Should the soil be dry at potting time, give a watering; but after that it should be applied with discretion till the plants begin to grow freely. Tubers that have been wintered in pots may be put into heat, watered a little, and afterward damped down with the syringe till they start into growth, and then repotted into suitably smaller sizes. Light is of great importance in the early months of the year, and it is all-important that the plants should be kept as near the glass as possible, after they have started into growth, to encourage a short-jointed and sturdy growth.
